Use of this type of instrumentation can reduce the reactor design safety margins required and allow more power output from a given design, thus providing significant savings in reactor cost, size, and weight.

The next step in reactor coolant instrumentation will probably be the application of transistors to this type of system in place of the present magnetic amplifiers. This change should result in improved performance, reduced size, cost, and weight, without sacrifice in the high degree of reliability obtained.

Steam-Generator Instrumentation for a Nuclear Power Plant with Analog Computer Verification of Dynamic Action

E. E. LYNCH
FELLOW AIEE

D. P. WAITE
ASSOCIATE MEMBER AIEE

Synopsis: High-performance nuclear reactor designs of the pressurized-water type are used with smaller than conventional steam drums to convert from primary coolant heat to steam in a heat exchanger. "Swell" caused by steam bubbles changing in size and raising the liquid level various amounts at different steam-generation levels poses an acute feedwater control problem.

A solution to such a problem is discussed. The method of studying feasible solutions and the use of a computer setup, which eventually includes newly developed physical equipment replacing the initial simulated measurement components, is traced.

Performance data with actual electrical control initiation with various degrees of proportional and reset action are shown as it operates an electric valve operator to control a simulated feedwater flow.

A COMPREHENSIVE system study was found desirable to aid in the system design and component development of steam-generator instrumentation for a nuclear power plant. This paper illustrates some of the problems and solutions associated with such a program.

The term steam-generator instrumentation as used in this paper is intended to mean the major instrumentation, sometimes called level control or at times feedwater control, which is used to control the performance of the steam generator in supplying suitable quantity and quality steam to meet power requirements. With small steam drums used for space economy in nuclear submarines, the problem is not one of simple liquid-level regulation or of straightforward feedwater-flow control.

The problem has at least three facets. First, variations in level must be programmed. Second, changes in feedwater flow must not adversely upset the thermal equilibrium of the reactor coolant since the reactor power level depends on the moderating properties of

the coolant and the moderating properties are a function of the coolant temperature. Third, subcooled feedwater entering the steam drum as shown in Fig. 1 can alter the flow through the downcomer and its control is an important factor in determining optimum operation of feedwater control valves.

Instrumentation Problems

Plant Characteristics Influencing Instrumentation

Modern steam plant design emphasizes the severe plant conditions influencing steam-generator instrumentation and this is especially true of marine propulsion plants. For instance, the steam generator shown schematically in Fig. 1 may use a steam drum with a volume several times less than that in present electric power plants of comparable rating. Rapid power demand changes result in severe transients in thermodynamic conditions in the steam generator, and 3-element feedwater control is usually specified.

Naval service presents environmental conditions considerably more severe than those encountered in present normal conventional industrial plants. Rugged instrumentation is desired for both, however. Electric transmission of measurements and control with minimum moving parts and high reliability components with long trouble-free service must be available. Easy-to-use built-in test and calibration features are additional requirements.

The present trend of both mobile and stationary nuclear power plants for near-term operation is to continue to use the steam generator and turbine combination. This trend is compatible with boiling water, pressurized water, and other reactor designs, and the evolutionary growth of the steam plant has resulted in vast knowledge and experience with that portion of the plant.

Conventional steam plants tend toward constant temperature and pressure for all loads. However, reactor plants cannot always allow the associated rapid changes in coolant temperature which can accompany this type of operation. A constant average temperature of the coolant reduces such disturbing changes in moderating characteristics within the reactor and is one mode proposed for nuclear plants. The associated steam temperature and pressure available from the drum will therefore drop with load.

During a rapid decrease in steam flow with the accompanying supersaturation of the steam as pressure increases, there is possible increased moisture carry-over from the drum which may be harmful unless the equipment is properly designed.

The use of saturated steam (rather than superheated) introduces additional carry-over problems where dry steam may be essential for continued operation.

One of the problems associated with carry-over is that of swell. Swell or shrinkage is the result of steam bubbles expanding or contracting in the water in the heat exchanger and steam drum. It results in the change in position of the interface between water and steam. Fig. 2 shows how the water volume in a drum can change with steam flow due to swell. With small drums where the effect is most important, fast rates of change of steam generation are accompanied by nearly as rapid change in level due to swell.

Since the feedwater valve cannot drain water, increased level due to swell must be handled by the drum almost independently of level control. The control system can, however, tend to regulate the level to a steady-state condition where the level is in the optimum position to anticipate the most probable maneuver to be expected next from a liquid-level point of view. Thus, programming level as a function of steam flow is helpful.

Fig. 4. Block diagram of 3-element feedwater instrumentation system

Swell is influenced by drum size. Its rate of change is influenced by the "internals" of the drum. Thus, variations of as great as four to one must be provided for. The rate of change of level with volume increase acts as a "gain" in the liquid-level feedback to the control and therefore may result in oscillation of the control unless designed to cover the range encountered. With mobile plants, change in this gain may result from list, trim, pitch, or roll, as well.

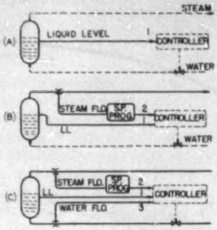

Fig. 5. Simplified diagrams of feedwater control

A—Single-element
B—Two-element
C—Three-element

Design of instrumentation must not only minimize oscillation but also it must not interfere, and in some cases should assist, with the functions of the steam drum. These functions include: 1. to hold a reserve of water for steam generation; 2. to provide a head to cause circulation, where forced circulation is not used; and 3. to make available a steam volume to help absorb swell.

Water level is extremely important to each of these functions. For instance, too low a level can lower the pressure head forcing water through the downcomer, and with water flow into the evaporator secondary thus reduced, the capability of steam generation is limited. Thermal shock from relatively cool feedwater on previously hot plates can cause fatigue with resultant cracks in the case of a suddenly lowered level. On the other hand, if the level is allowed to get too high, the separators may be flooded, the steam to the turbine may become wet, and "entrainment" may occur. Turbine blades may become damaged under these conditions. The shock of downstream components due to wet steam is a possibility to be avoided.

LEVEL CONTROL CONSIDERATIONS

To solve the problems posed by the foregoing plant characteristics, a system approach as indicated in Fig. 3 was followed. This was done since plant characteristics were expected to affect the dynamic action of the feedwater valve in a manner significantly different from that experienced in conventional plants; the instrumentation to be developed included sufficiently new approaches; and compatibility of plant and instrumentation characteristics was very essential to the necessary performance and reliability of the system.

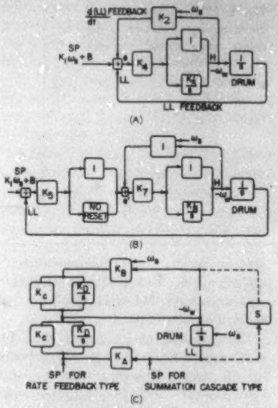

Fig. 6. Simplified transfer function diagrams of 3-element feedwater instrumentation systems

A—Rate-feedback type
B—Summation-cascade type
C—Equivalent diagram for both types

After determining functional specifications as dictated by plant conditions and steam requirements, a 3-element system approach was synthesized by plant engineers and is shown in block diagram in Fig. 4.

Mathematical equations which can be used to define such a diagram are

$$H=K_4K_3'\int(F-LL)_{dt}+K_4(F-LL) \tag{1}$$

$$F=K_2(\omega_s-\omega_w)+C \tag{2}$$

$$C=K_1\omega_s\pm B \tag{3}$$

where

H = valve opening resulting in proportional feedwater flow
LL = liquid level
ω_s = steam flow
ω_w = water flow
B = bias values to modify steady-state liquid level
K_1 = an adjustment to program the value of desired liquid level, as linear function of steam flow
K_2 = an adjustment which determines the relative magnitude of steam-water-flow mismatch feedback signal to liquid-level error signal
K_3' = an adjustment for reset rate of the control initiator
K_4 = an adjustment of proportional band

After simulating these in simple form on an analog computer and getting preliminary data on dynamic action, other possible system approaches were studied. Some considerations resulting from the study follow.

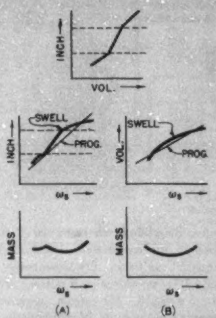

Fig. 7. Typical characteristic curves for 3-element feedwater instrumentation system

A—With level regulation
B—With volume regulation

Single-element, 2-element, and 3-element feedwater instrumentation are all available commercially to meet conventional land-based nonnuclear requirements as they presently exist.

Single-element control, although used satisfactorily with small boilers on some conventional installations, was found inadequate to meet requirements of the problem. Although extremely simple as shown in Fig. 5(A), the control depended on a steady-state level condition differing from the set-point level in order to sustain the feedwater valve at a given opening corresponding to a particular steam flow. With proportional band control only, this level condition was opposite that desired to accommodate swell with minimum change of mass in the steam drum. It was in the wrong direction to keep a high water level at high steam flows in order that as steam flow dropped, the level would not go down too much due to negative swell. It required high sensitivity tending toward excessive valve motion.

When reset action was added to bring the level back to a set point, a computer simulation of plant and instrumentation involved showed sluggish and slow dynamic movement of the feedwater valve when overpowering proportional action was used. With proportional plus reset action, bad oscillation occurred unless the action had such a long time constant that it was not useful in bringing level to its set value in a reasonably quick time.

Fig. 5(B) shows schematically a system which allows programming of the set point to accommodate swell with a low mass change in the steam drum. However, control problem experience indicates that a tachometer or rate feedback signal is

usually necessary to provide dynamic performance that is fast enough to correct for large rapid disturbances and simultaneously operate within narrow limits from the set point. Two-element feedwater control did not inherently provide this signal feedback.

With three elements available for control as shown in Fig. 5(C), a rate feedback equivalent can be generated independent of the level transmitter signal. The difference between the steam mass flow and the water mass flow is used as a feedback. This is proportional to the rate of change of drum liquid mass. From the dynamic response standpoint, this feedback is better able to control the valve than is the level error signal. One reason for this is the fact that before the level error can control the valve, there must be a detectable error. This takes time. However, neglecting swell and programming of set point, that which is integrated with time to give a level error, i.e., rate of change of liquid level, is available immediately for control.

Another advantage of utilizing the rate signal with the level signal is the fact that it is one of the most effective ways known in servo techniques to counteract or compensate for an oscillating tendency of an otherwise single-element control, where reset is utilized in the control initiator to restore level to a set point or programmed value. This tendency results from the integrating effect of the steam drum. The drum and the reset component of the command signal result in two integrators in series (with 180-degree phase shift at all frequencies) and if reset rates are high, oscillation will result unless compensated for.

An advantage of obtaining the rate signal from steam- and water-flow measurements is the smoothness of the generated signal which is independent of random or cyclic rapid apparent level changes due to splashing, vibrations, bubbling, etc.

Fig. 6(A) shows simplified transfer functions of such a rate feedback 3-element control. K_4 represents a proportional band adjustment and K_3' an adjustment for reset action. The set point (SP) is programmed proportional (K_1) to steam flow (ω_s) with an adjustable level bias (B). H represents valve position and the simplification assumes this equal to water flow (ω_w). K_2 is an adjustment available to alter the dominance of the flow mismatch signal with respect to the liquid-level (LL) signal. To illustrate the need for a dominance adjustment, consider the effect of a rapid increase in power output calling for more steam. Swell will increase level almost immediately, calling for a more closed feed-

water valve. But flow mismatch will initially call for a more open valve. The dominance adjustment can be used to control the direction of valve motion during the initial stages of a maneuver.

Fig. 6(B) shows another approach to 3-element feedwater control. It is designated here as a summation cascade system since the liquid-level controller output is added to a flow mismatch signal to act as the input to the second controller. With reset in both controllers and with the integrating effect of the steam drum, 3-series integrators present a stability problem.

Fig. 6(C) is a circuit equivalent to Fig. 6(A) or 6(B) when K_A represents K_4 or K_5K_7; K_B represents K_2K_4 or K_7; $K_C=1.0$; and K_D represents K_3' or K_8'. Thus equivalence is established between this rate feedback and summation cascade control when the first cascaded controller has no reset action and when $K_7=K_2K_4$; $K_8'=K_3'$; $K_7=K_4/K_5$; and $K_5=1/K_2$. Computer studies showed no advantage for the more complex cascade type with plant characteristics used in the study.

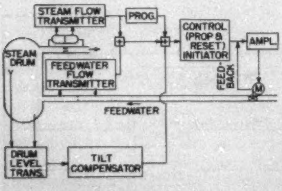

Fig. 11. Block diagram of 3-element steam-generator instrumentation system

Other possible variations in instrumentation can be determined by the programming used. Level regulation is the term used here to designate a system which programs liquid level proportional to mass steam flow. Volume regulation as used here regulates the liquid volume in the drum proportional to mass steam flow. A variation of volume regulation could regulate volume as a function of steady-state swell. Mass regulation holds the mass in the drum constant. Each of these methods had its advantages. Level is important to limit carry-over and exposure. Volume affects the available steam space to absorb swell. Mass establishes the hydrostatic pressure head that affects generator recirculation rates. Which regulation is best?

Volume regulation has a constant loop gain in the feedback from the drum detector. Level regulation results in a variable gain as shown by the variable slope of the inch-versus-volume curve of Fig. 7 which is caused by the internals of the drum. Level regulation is a practical form of control since detectors of level can be used linearly; computer studies indicate that stability is not a problem at the gains involved with plant characteristics usee in this study; and approximate mass regulation is possible by optimum linear programming as indicated by Fig. 7. To provide for optimum available swell volume, the volume would require nonlinear programming with steam flow which would depend on the swell characteristic.

An analog computer with a typical setup, shown in Fig. 8, was used in this study and proved to be a valuable tool in determining stability and dynamic characteristics of posssible variations in control techniques such as those discussed. In addition, the simplified circuit of the rate-feedback type shown in Fig. 9 with its Bode diagram shown in Fig. 10 explained observations on stability due to such changes as altering the dominance of flow mismatch, changing from low to high drum gain, changing the finite gain of the control initiator, etc.

Fig. 12 (right). Differential-pressure-type flow transmitter with assembled square-root extractor

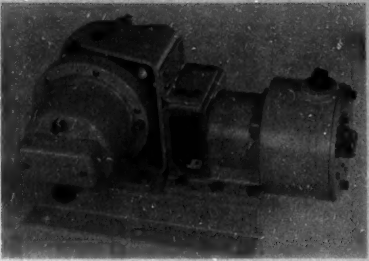

Fig. 11 shows in block diagram one form of the interconnections of equipment which is capable of performing satisfactorily the functions of steam-generator instrumentation of a system with characteristics which were studied.

Equipment Description

Flow Detectors

Typically the flow of both steam and boiler feedwater are measured using flow

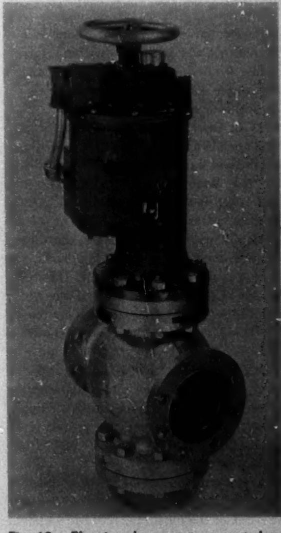

Fig. 13. Electric valve operator mounted on $3^1/_2$-inch regulator globe valve

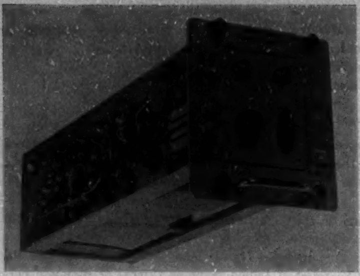

Fig. 14 (left). Typical measurement amplifier built for high shock and vibration

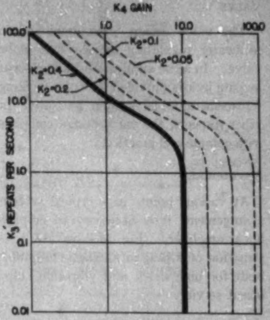

Fig. 15. Typical curves of locus of oscillation point as control initiator adjustments are changed

nozzles to produce a differential pressure proportional to the square of volumetric flow rate. The resultant differential pressure can then be sensed with a differential-pressure cell and pick-off arrangement as shown in Fig. 12. This design incorporates multigradient spring assemblies in a manner to provide a straight-line approximation to the square-root relationship between differential pressure and displacement. The result is an output voltage closely approximating the volumetric flow rate. It is desirable to make steam density compensations since error in mass flow of saturated steam becomes significant when no density corrections are made. To accomplish the correction, a bourdon-tube type of pressure detector provides an output voltage used for compensation. A straight-line approximation from varying spring gradients is also part of the pressure transmitter design. The advantage of this approach to square-root extraction as compared with other means is that simple noninteracting adjustments permit compensation for nonuniform elements elsewhere, such as flow coefficient calibration curves of the flow nozzles employed.

Liquid-Level Detectors

Liquid-level detectors often used may consist of a differential-pressure detector similar to that described for the flow detectors except that no additional spring clusters are employed to modify the linear relationship between differential pressure and electrical output signal. Differential pressure is produced by the difference in hydrostatic head between a filled reference water leg within the steam drum and that produced by varying level above a drum bottom pressure tap. Since this signal varies with the cosine of pitch and roll angle as well as density variations of the fluids, significant compensations may be desired in some installations. Density compensation is again made possible by measuring a system pressure since conditions of fluid densities can be directly related whenever saturation conditions prevail. Tilt compensation is accomplished by measuring the deviation from the vertical with a simple spring mass system and electric pick-off device. The output signal from the tilt compensator is divided into the signal from the differential-pressure cell in order to cancel the cosine factor in the signal.

Control Initiators

Equipment has been developed to produce proportional plus reset action using magnetic amplifiers. Adjustments include both proportional band (gain) and reset rate (coefficient of integration). The controller is actuated by an error signal that is also produced in this unit by comparing the steam-flow and water-flow signals to supply a rate feedback signal by adding this to a summation of measured liquid level. A manual level adjustment and a signal actuated by steam flow combine in a manner to produce a steady-state level command program with adjustable zero and range proportional to steam flow.

In some cases, the proportional plus reset action is considered unnecessary, in which case, necessary integrating is done by the servomotor associated with the electric valve actuator described in the following, and no proportional action is employed.

Valve Actuator

The mechanism of Fig. 13 is employed in a position-type loop when the proportional plus reset controller as described in the foregoing is used; a magnetic servo-amplifier provides excitation to the control phase of a servomotor in response to an error signal resulting from the comparison of position plus rate feedback of the controller output signal. Various valve actuator mechanisms have been designed to provide considerable flexibility in selecting the large power device associated with equipment described in the foregoing.

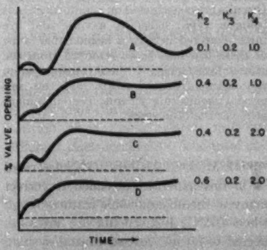

Fig. 17. Typical dynamic curves showing effect of varying control initiator adjustments

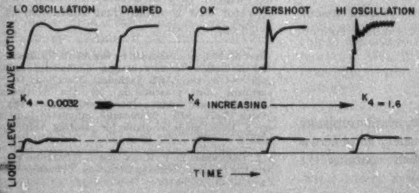

Fig. 16. Typical dynamic curves showing effect of changing control initiator gain adjustment, K_4

VALVE

The valve design often employed in feedwater regulating service is a globe valve. In some applications, a back-seat locking jack is provided to enable packing replacement under system pressure. In other respects, the valve design complies with commercial practice.

AMPLIFIERS

At various points in a typical system arrangement, it is necessary to employ linear amplifiers. Fig. 14 shows the construction of a plug-in magnetic amplifier built for high-shock and vibration shipboard service.

System Performance

During the system study, an analog computer was utilized to determine data on dynamic characteristics and oscillation. Fig. 8 shows one computer setup utilized to simulate a rate feedback approach. With this arrangement both step and ramp functions of steam flow were used as the disturbing characteristic. By utilizing a volume-to-inch converter or by short-circuiting it out, both volume and inch regulation as discussed were investigated and compared.

As physical instrumentation became available, the control initiator and valve simulation on the computer were replaced by actual equipment. Response characteristics taken under these conditions verified results taken with simulated equipment.

Typical of the data obtained were curves of dynamic motion of the valve and oscillation data for various values of equipment adjustments.

Fig. 15 shows typical curves of the locus of an oscillation point as adjustments are changed in a direction to increase the control initiator gain K_4, or its "repeats per second," K_3'. These are shown for various values of K_2 (the adjustment for changing the dominance of flow mismatch over liquid level in determining dynamic response).

Fig. 16 shows typical dynamic curves of valve motion with varying gain in the control initiator in response to a ramp increase in steam flow from 20% to 100% in a relatively short time and with level programmed approximately to equal the swell.

Fig. 17 shows typical dynamic curves of valve motion for various adjustments of the control initiator for a condition involving a large swell with a ramp increase in steam flow. It shows some of the variations obtainable by changing the dominance adjustment K_2.

Conclusions

This comprehensive system study of steam-generation instrumentation played an important part in the development of a system meeting the functional requirements dictated by the severe plant conditions which were imposed by nuclear submarines.

The dynamic and oscillation data obtained serve as typical of dynamic performance obtainable with nuclear power plant propulsion steam generators controlled with this form of instrumentation.

NONMEMBER AIEE

Synopsis: The basic circuitry of ORNL (Oak Ridge National Laboratory) reactor control instrumentation has been rearranged, and in some cases redesigned, so that more flexibility, reliability, and economy are achieved without sacrificing the safety performance of the original designs. Circuits are constructed on a uniform chassis (plug-in type) called a module and are interconnected in such a fashion that some of them can fail, or be removed from the system for checking, without causing system shutdown. In conjunction with an improved monitoring scheme, the equipment achieves the objectives.

THE MODULAR DESIGNS described in this paper are intended to correct many of the objectionable features found when ORNL instruments are interconnected to form a reactor control system. The four principal channels of this system are:

1. Safety system.
2. Pulse channel.
3. Logarithmic channel.
4. Linear or servochannel.

The basic amplifier circuits of ORNL instruments have been designed on modular chassis. This chassis is 6 inches wide and 12 inches deep and has an 8- by 8-inch front panel. A single 32-pin male connector on the rear of the chassis provides the necessary external connections. The module slides into a shelf assembly where it mates with a female connector.

Safety System

A typical 4-rod safety system utilizing four ORNL composite safety amplifiers is shown in Fig. 1. Each contains the following circuits:

1. Level preamplifier: a linear d-c amplifier which produces a voltage proportional to the ion chamber output current and hence reactor power level.

2. Period preamplifier: a linear d-c amplifier that develops a voltage inversely proportional to reactor period.

3. Sigma amplifier: a nonlinear d-c amplifier driven by either the level or period preamplifier. In Fig. 1, composite safety amplifier 4 has the period preamplifier driving the sigma amplifier. When the reactor power level is in the 0% to 100% region, the sigma amplifier output changes by 0.3 volt per 10% change in power level. For a 10% change in power level above 100%, the output changes by 0.6 volt.

4. Magnet amplifier: a linear d-c amplifier which controls the current to an electromagnet supporting a safety rod. This current varies inversely as the input signal from the sigma amplifier.

5. Fast-scram circuit: a linear d-c amplifier which operates a relay to warn the operator that a scram (fast shutdown) is being approached.

ELECTROMAGNETS

6. Magnet power supply: an unregulated d-c power supply which provides the magnet current.
7. Amplifier power supply: a regulated d-c power supply which furnishes the plate and bias voltages for the amplifiers.

The only interconnection between the composite safety amplifiers is at the output of the sigma amplifiers. Here all four outputs are tied together creating what is commonly called a sigma bus. The safety amplifier with the highest output has control of the sigma bus. This connection provides a safety system mode of operation known as auctioneering. The one signal on the sigma bus is the input to all four magnet amplifiers and, therefore, every electromagnet current is determined by it. Consequently, a reactor scram is possible from any one safety amplifier. To ensure that the safety system is operating properly, a relay and meter measuring monitoring system has been designed into each composite safety amplifier. Some functions of the monitor warn the operator through an external annunciator if portions of the safety system have been disabled while others require a regular schedule of inspection through meter measurements.

The principal objections to this safety system are:

1. An electronic failure in any of the composite safety amplifiers results either in automatic shutdown of the reactor or disables part of the safety system. In either case, unnecessary and annoying shutdowns result. For example, a burnout of the magnet power rectifier tube will automatically drop a safety rod causing reactor shutdown. Again, if the input tube to a magnet amplifier fails, a safety rod will not be able to be released except by the removal of magnet power (slow scram).

2. Protection against the consequence of certain sequences of component failures is not provided in the composite safety system. The composite safety system of Fig. 1 will "hang up" all four safety rods with the following sequence of component failures:

a. Loss of bias voltage in one magnet amplifier.

b. Open-plate load resistor in a second magnet amplifier.

c. Failure of input tube of a third magnet amplifier.

d. Failure of interstage tube in a fourth magnet amplifier.

Other combinations of failures exist which would have the same effect. The only annunciated failure is listed under item a.

3. Since each composite safety amplifier contains a level preamplifier, a period preamplifier, a sigma amplifier, and a fast-scram circuit, it can easily be shown that almost all safety systems using this equipment will result in many amplifiers serving no purpose at all. For example, a 6-rod safety system would necessitate six composite safety amplifiers. Normally three ion chambers would operate three of the level preamplifiers and three of the sigma amplifiers. One period preamplifier would derive its input from a single logarithmic channel and drive a sigma amplifier. Therefore, this system would have five period preamplifiers, three level preamplifiers, two sigma amplifiers, and two fast-scram circuits consuming power, but in no way a part of the system.

4. The physical construction of the composite safety amplifier is such that it is difficult to perform routine servicing and maintenance. Also, it cannot be disconnected from the system without causing reactor shutdown.

Modular Safety System

The proposed modular design of the 4-rod safety system as shown in Fig. 2 will correct these objectionable features.

First, the modules designed at level safety and period safety contain only a single preamplifier, a sigma amplifier, and a fast-scram circuit. Therefore, the number of safety amplifiers is exactly equal to the number of primary input signals. Each safety amplifier has its own filament transformer. Plate and bias voltages are obtained from the safety power modules with the positive voltage also providing the power for the UIC (uncompensated ion chambers). The signal outputs from the safety amplifiers are again auctioneered and, therefore, the voltage at the sigma bus is determined by the highest safety amplifier output. The conventional monitored information is fed to the junction box and external annunciation is provided should an abnormal condition arise. Because of the plug-in feature of the modules, it is then obvious that any level safety can fail or be removed for servicing without causing reactor shutdown. Directly below the sigma bus are the magnet control modules. Each module contains two identical magnet amplifiers whose outputs feed two different electromagnets. The total current in any one electromagnet is the sum of two currents from two magnet amplifiers located on different modules. For example, magnet amplifier output current A_1 plus magnet amplifier output current A_2 equals electromagnet current A. A feedback resistor located in the junction

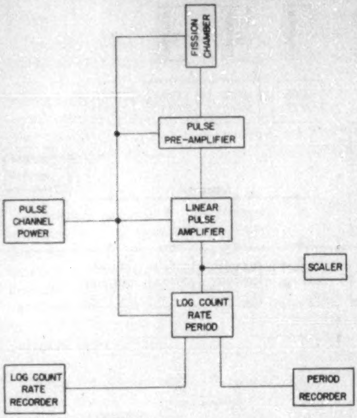

Fig. 3 (left). Modular pulse channel

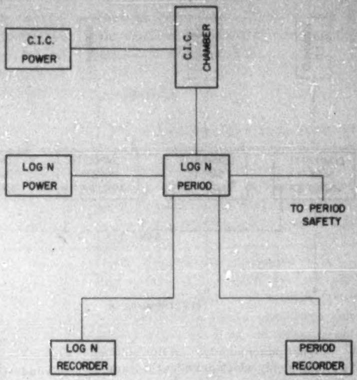

Fig. 4 (right). Modular logarithmic channel

box and in series with the magnet current provides the feature of load sharing of the magnet amplifier outputs. A decrease in output current from a magnet amplifier, say A_1, results in an increase by approximately the same amount in output current from magnet amplifier A_2. Of course, if the decreased output current is the result of a signal from the sigma bus, then both amplifier outputs are reduced. By virtue of this load sharing it can be seen that magnet control modules 1 and 3, 1 and 4, 2 and 3, or 2 and 4 can fail or be removed from the system without causing reactor shutdown. In order to ensure that a magnet amplifier output current will not increase to such an extent that no amount of input signal from the sigma bus is capable of releasing a safety rod, miniature-type thyratrons have been inserted into each magnet amplifier that will disable the output tube should this unsafe condition arise. The component failures listed under item 2 will cause the thyratron associated with each amplifier to fire, resulting in essentially zero output current from each amplifier.

The magnet power modules are the source of the electromagnet current. Each module contains two identical conventional unregulated power supplies. The total current in any one electromagnet is load shared between two power supplies located on different modules, and each power supply has the capacity of supplying the entire load current. Continued reactor operation is therefore possible if magnet power modules 1 and 3, 1 and 4, 2 and 3, or 2 and 4 fail or are removed from the system.

The modules designated as safety power consist of a positive and a negative conventional unregulated power supply on each chassis. These two voltages are fed to the safety amplifiers and magnet control modules where they are regulated and, therefore, furnish the necessary plate and bias voltages for the amplifiers. The total current demand from each supply is load-shared between three modules. In the 4-rod system shown in Fig. 2, two are capable of supplying the total demand. The failure or removal from the system of one can therefore be tolerated.

A monitoring scheme for this safety system has been designed on a separate module called the safety monitor. The front panel contains the following indicators and controls:

1. Four miniature side indicator meters which indicate continuously the outputs of the safety amplifiers. Three of these meters indicate the power level seen by each neutron-sensitive chamber and the fourth displays the reactor period.
2. Two neon lamps which inform the operator that the load sharing of the magnet power and safety power modules is correct. If it is not correct, this fact is annunciated and the lamps are extinguished.
3. Two wafer-type selector switches. One selects the function to be measured and the other selects the circuit under observation. Together with a panel monitor meter the following quantities can be measured:
   a. The cathode currents of every magnet amplifier tube.
   b. The output voltage of each safety preamplifier.
   c. The total current in each electromagnet.
   d. The sigma bus voltage.
   e. The output currents of every magnet power supply.
   f. The output current of every safety power supply.

Therefore, this monitor allows the operator to calibrate each safety amplifier, to locate incipient failures in the magnet amplifiers, and to locate power supply failures immediately.

Finally, it is possible to construct systems different in concept from the one described in this section. This can be accomplished simply by the manner of the external interconnection of modules. However, each new system evolved by this process must be carefully examined for safety and reliability characteristics.

Modular Pulse Channel

Fig. 3 is a block diagram of the pulse channel. Since the pulse preamplifier

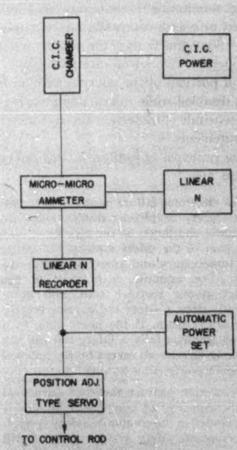

Fig. 5. Modular linear channel

is generally located near the reactor and is not a component of the control panel instrumentation, this unit was not modified. The ORNL linear pulse amplifier circuit and the ORNL log count rate meter with period circuit were duplicated on separate modules. A common electronically regulated power supply called pulse channel power was designed and this module provides all the necessary power for the amplifiers and the fission chamber. In addition to the advantages gained by plug-in type of amplifiers and power supplies, a considerable reduction in the number of electrical components resulted.

Modular Logarithmic Channel

The block diagram for the modular logarithmic channel is shown in Fig. 4. The ORNL log n pile period circuit was constructed on a module called log n period. An electronically regulated power supply called log n power was designed and this module supplies the necessary power for the log n circuitry. The compensated ion chamber (CIC) receives power from a modified ORNL CIC power supply designed on a modular chassis. Continuous adjustment of the compensating voltage by a helipot and range changing of the measuring meter affords very fine adjustment of this voltage and also easy reproducibility.

Modular Linear Channel

Three modules have been designed for the modular linear channel as shown in Fig. 5. The CIC power module is identical to that in the logarithmic channel. The display and control functions of a standard micromicroammeter have been designed on a second module. Remote location of the amplifier is therefore possible. The final module in this control system is the automatic power set. It is a regulated d-c power supply and constitutes the set point for the servo system.

Conclusions

The modular designs described in this paper provide a reactor control system having the following five advantages:

1. Many electronic failures will not result in reactor shutdown or disablement of parts of the safety system.
2. Sequences of electronic failures causing unsafe operation are considerably less probable to occur.
3. All electronic circuitry in the system is performing a function.
4. Many circuits can be removed for servicing and replacement without affecting the system.
5. The modular designs of circuits affords the opportunity of constructing a variety of systems.

Variation of the Trip Point in the ORNL*-Type Safety System

J. L. COCKRELL
MEMBER AIEE

C. W. RICKER
NONMEMBER AIEE

IN nuclear reactor safety systems electromagnets are often used to connect neutron-absorbing rods to positioning drive units. The currents through these electromagnets can be varied in a continuous or discontinuous manner as a function of the reactor neutron level, the ultimate objective being to enable a trip or scram should an unsafe operating condition be present or imminent. A group of instrument channels, interconnected so as to determine whether the "unsafe operating condition" exists and, upon such determination, to trip the rods (all with no operator attention), comprise a safety system. One such safety system is the so-called auctioneering array of safety amplifiers, all deriving information from separate channels, and jointly feeding a single common point of interconnection or bus. The state of this bus is determined by the highest bidder (the channel with the highest output voltage). Thus a single channel, detecting an unsafe condition, is able to assume control and eventually shut down the system.

The functioning of the individual channels, their inputs, and the interaction of a group of these channels, must be known so that due consideration may be given in setting up the equipment to cause trip to occur under the proper conditions. It is the objective of this paper to supplement the understanding of single-channel performance by presenting the significant aspects of system performance.

Safety Channel

The composite safety amplifier, shown in Fig. 1 (ORNL *Q-1565*,) is representative of a class of instruments designed to perform the safety functon described hereinbefore. It contains both a level preamplifier and a period preamplifier, but one of these two is used at a time. The composite safety amplifier is a single channel in itself and is generally used in a system of three or four channels which are shown in block diagram form in Fig. 2.

The right-hand composite safety amplifier has the period preamplifier connected; the other amplifiers have their level preamplifiers in use.

The preamplifiers, whether level or period types, are linear and are designed to accept input signals proportional to the neutron flux of the reactor. The level preamplifiers receive currents up to about 50 microamperes at 150% full power from ion chambers (suitable for about three decades below full power), and deliver output voltages of 22 volts at zero power and $22+15$ or 37 volts at 150% full power. The period preamplifier derives its information from the log n amplifier (suitable for about six decades below full power). This input, in the form of a voltage, is first differentiated and, after amplification, is delivered as an inverse period signal which covers exactly the same range of voltages as delivered by the level preamplifiers. Here an infinite

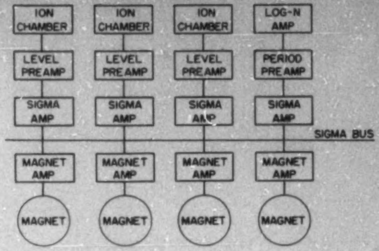

Fig. 2 (right). ORNL-type safety channels and system

period, corresponding to zero rate of change of reactor power, will be evidenced by 22 volts at the period preamplifier output. A period of about one second will cause a preamplifier output of about 37 volts, depending on the exact differentiating circuit elements and the amplifier gain.

The sigma amplifiers are identical and establish the voltage of the point of system interconnection—here called the sigma bus. This voltage is the input to all the magnet amplifiers, which are linear and in turn supply currents to the individual electromagnets. The sigma amplifier herein described is of particular interest and is considered in detail, both as a component and as an interconnected part of the over-all safety system.

Even when the magnet currents are continuous functions of reactor power level, as in the composite safety amplifier system, it is desirable that they vary only a small fraction of their nominal zero power value when the reactor is experiencing normal power excursions or transients. In order that the magnet currents will decrease rapidly when abnormal power excursions or transients occur, a nonlinear link in the channel is necessary. The safety or sigma amplifier is this nonlinear link, and it carries the dual role of generating the input-output nonlinear relation and of providing coupling between the individual channels. All other parts of the circuit, before and after this sigma amplifier, are linear and do not interact between channels except, of course, through the reactor power. Fig. 3 shows the typical circuit arrangement of the sigma amplifier, and Fig. 4 is the approximate characteristic of a single such amplifier.

V_1 is a conventional cathode-follower driver, which delivers the input voltage to the sigma amplifier tube V_2 through R_4. V_3 is a clamping diode which maintains the grid voltage and thus the output voltage essentially constant for low signal inputs. This amplifier is designed to be operated with the level preamplifier and ion chamber so that each input volt above the 22 volts shown is equivalent to 10% of reactor power. Thus, full power occurs at 32 volts and the overload power of 150% occurs at 37 volts. Note that the diode clamping action ceases at about 70% or 80% of full power. When driven by the period preamplifier an input of 22 volts corresponds to an infinite period while 37 volts corresponds to the trip period (usually one second).

Conventionally, the sigma amplifier is followed by a linear magnet amplifier which decreases in output electromagnet current about 5 milliamperes for every volt rise in the sigma bus. The actual magnitude of magnet current, for any input voltage, can be adjusted, and is generally set to give a trip or scram at a particular value of voltage input to the magnet amplifier. This voltage input is the same as the output voltage of the sigma amplifier and is the point of system interconnection. Thus, the name sigma bus has been attached to this point.

Interconnection and Interaction

The output impedance of a cathode follower is normally expressed in terms of the parameters of the circuit and tube, and is in the usual form

$$Z_{\text{out}}=\frac{R_K r_p/\mu}{R_K+r_p/\mu}=\frac{r_p}{\mu+\dfrac{r_p}{R_K}} \qquad (1)$$

where R_K is the value of the cathode resistor, r_p is the dynamic plate resistance of the tube, and μ is the amplification factor.

If r_p is not a constant, the impedance presented by the cathode follower to an incremental voltage change, impressed on the cathode of the tube, is more conveniently expressed as

$$Z_{\text{out}}=\frac{R_K}{\dfrac{\mu R_K}{r_p}+1} \qquad (2)$$

where r_p appears only once.

When the cathode is being driven positive by a voltage from an external source (for instance, another cathode follower), the tube current decreases, r_p increases, and the Z_{out} value approaches the value of R_K. On the other hand, when the cathode is driven negative, the tube conducts more strongly, r_p becomes stabilized, and the Z_{out} approaches r_p/μ (for the usual case when $\mu R_K/r_p>>1$). This variation is shown in Fig. 5 for a typical *Q-1565* sigma amplifier.

The significance of this change in output impedance, when several of these amplifiers are connected together at the cathodes, is that some interesting system results are possible. In particular, if a single tube cathode voltage increases because of a positive-going voltage on its grid, this action tends to decrease the impedance of the driving tube and at the same time to increase the loading impedance of the driven tubes (decreasing the loading). One might ask if (in the limit) the loading of the driving tube by the driven tubes could be made negligible. The data for Fig. 6 were taken in the laboratory on a simulated system of four sigma amplifiers and driving stages in order to establish a quantitative basis for discussing these notions. These curves for various loading conditions show that although the condition of no loading is approximated under some conditions, significant loading does occur, and that (if accurate knowledge of the interconnected cathode voltage is desired) this loading must be carefully considered.

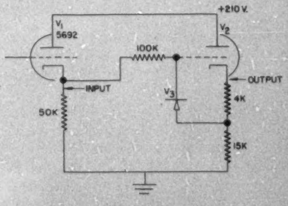

Fig. 3. Sigma amplifier

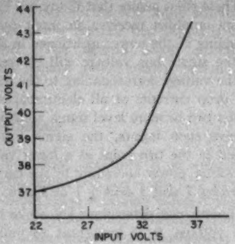

Fig. 4 (left). Sigma amplifier characteristic

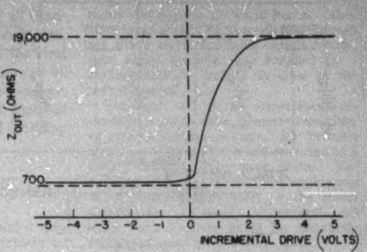

Fig. 5 (right). Input impedance variation

For the case of this type of circuitry in a nuclear reactor safety system, the final result is variation in the trip or scram point, depending on the nature or combination of inputs to the contributing safety amplifiers.

Normal Extremes

The safety system of a typical swimming-pool research reactor might contain two or three level safety channels and one period channel (as shown in Fig. 2). This gives rise to two normal extremes of safety action. One is the case arising from a very slow rise to an overload condition, but where the period safety amplifier is supplying negligible information. The level channels will be receiving the information from their separate ion chambers corresponding to this rising power level. If the channels are properly adjusted and calibrated, they will show a simultaneous slow rise in cathode voltage. (The level channels are driving the sigma bus upward in voltage.) The period safety, on the other hand, is receiving no significant information, and its cathode will be driven by the rising cathodes of the level channels. Any loading that would occur is by the single period channel alone (or all period channels if there should be more than one). This loading for the instances of two or three level channels is shown in Fig. 6 by the curves titled *2 driving 1* or *3 driving 1*. In either event the departure from the *unloaded* curve (single-unit characteristic) is quite small.

The other extreme is that encountered when the reactor power level is a decade or more below full power, but is rising rapidly enough to cause significant output from the period safety channel. Here the single period safety amplifier (or all such, if there are more than one) would act as the driving channel, while all level channels would be driven through the cathode interconnection; see curves labeled *1 driving 2* or *1 driving 3*, Fig. 6. In this instance the loading impedance seen by the driving period amplifier would be the impedance of all other amplifiers connected in parallel.

These two extremes for the example of a system using three level and one period channels are shown in Fig. 7(A). Also shown against the sigma bus voltage level is the linear magnet amplifier characteristic, Fig. 7(B). A rising sigma bus voltage corresponds to a falling magnet current. It is important to note that, for a given magnet current adjustment, the point at which the electromagnets release is determined only by the sigma bus voltage level.

Figs. 7(A) and (B) are read for a given situation (for example, *3 driving 1*) by noting a given input signal V_1 produces a sigma bus level L_1 which causes a magnet current I_1. A higher input signal V_2 produces a sigma bus level L_2 and a magnet current I_2. Note again that when the magnet current adjustment has been made, the position of the magnet amplifier characteristic in Fig. 7(B) is deter-

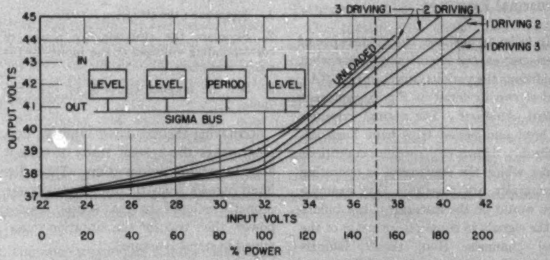

Fig. 6. Loading characteristics of safety amplifiers for various driving conditions

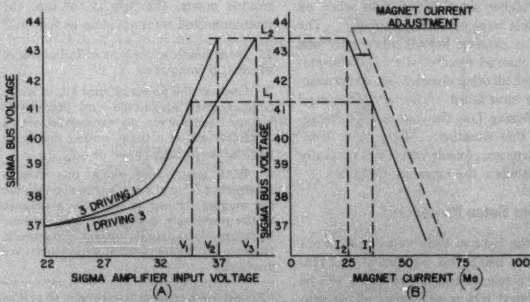

Fig. 7. Over-all transfer characteristic

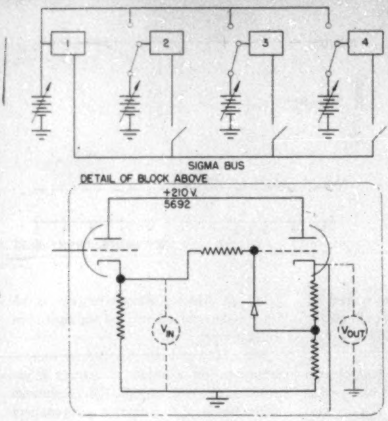

Fig. 8. Interconnection test scheme

mined and the sigma bus level must be up to L_3 to cause a trip. If only one safety amplifier receives an input (*1 driving 3*), its input must proceed to V_3 before the trip point is reached.

Abnormal Extremes

In order to evaluate the significance of these curves, one must know under what conditions the various curves in Fig. 7(A), and shown in detail in Fig. 6, represent actual situations. The normal extremes of level and period trips have been described. However, certain conditions under which the equipment is operating abnormally are possible. One example here would be the instance of the failure of the signals to reach one or more of the level channels. Here those channels which did receive signals would have to drive those which did not, in order for the system to reach a trip. Under these conditions the trip point would be reached at a higher signal input than when all channels were operating normally. The obvious extreme here is when only one level channel receives the level information and all other channels are either inactive or have failed. The curve *1 driving 2* or *1 driving 3*, as the case may be, represents this situation. Many other combinations are possible which will generally fall between the extremes described.

System Setup Procedures

In the light of the foregoing, it is not possible, using this equipment, to prescribe a reactor trip power which will be the actual trip power under all circumstances. Accordingly, it is well to examine how the trip point is inserted into this safety system, what the alternatives for the setup might be, and the resultant actual trip points.

Qualitatively, setting the trip can be summarized by three distinct steps:

1. Determine the situation for trip.
2. Simulate the situation by means of corresponding voltages at the inputs to the sigma amplifiers.
3. Set the magnet currents to the drop value.

Removing the simulated input voltage now makes the system ready to accept actual operating information. When the input signals from the ion chambers are properly related to the actual reactor power, then trip for the situation determined in step 1 is assured.

A particular example of carrying out these steps is helpful in bringing to light some of the details involved. If the criterion for trip is an absolute maximum reactor power, this trip is set into the interconnected safety system as follows:*

1. Determine the per cent of full power at which trip is required.
2. Convert the power of step 1 to a simulated voltage magnitude and apply this voltage successively to each level sigma amplifier (one at a time), noting the sigma bus voltage in each instance.
3. With the lowest sigma bus voltage determined in step 2 applied to the bus, set the magnet current in each electromagnet to the previously determined drop current by means of the magnet current adjustment. (Be sure that all bus protect adjustments are disabled.)

These steps assure that if any one level sigma amplifier receives an input corresponding to the power mentioned in step 1, the sigma bus voltage will be raised to the voltage corresponding to the magnet drop currents of all electromagnets. When two or more level sigma amplifiers receive such inputs, the sigma bus is raised to the trip point at a lower value of reactor power according to the curves *2 driving 1* and *3 driving 1* of Fig. 6.

Having once determined the sigma bus trip voltage, it is important to understand that the reactor period which, operating through the log *n* circuit and the period safety circuit, raises the sigma bus to this trip voltage is the trip period. When the sigma bus trip voltage is reached by the period sigma amplifier acting alone (at low power), the reactor period causing this rise is the limiting period and must be consistent with the operating and safety philosophy at the site concerned. At higher powers, approaching full power, the level sigma amplifiers contribute to the sigma bus voltage—and a slightly longer period will trip the system. Furthermore, for a given sigma bus trip voltage and any specified loading condition (both as described in the foregoing), the period for trip can only be changed by altering the components in the differentiating circuit at the input to the period preamplifier or by changing the gain of that particular period preamplifier.

Some figures from the illustrations may point up these facts. Referring to Fig. 6, if the trip is set with a 150% power signal (37 volts) into a single level sigma amplifier, then the trip is assured at 150%, and the sigma bus voltage for this will be 41 volts. When three level safety channels were operating together (*3 driving 1*), the trip (sigma bus raised to 41 volts) would occur at 126% of full power. As an alternate safety setup procedure, it might be assumed that three level channels would be operating normally to bring the sigma bus voltage up during a power excursion. To simulate this condition, the 150% power signals would be applied at the same time to the inputs of all three level sigma amplifiers. Note that the sigma bus voltage for trip is now 43 volts. Now a power rise to 150% full power would trip the system when all channels are operating normally, but it would require a rise to 180% of full power in order to ensure the trip if for any reason only one sigma amplifier could see the power rise. If a 1-second period is required to raise the sigma bus to 41 volts, the same period circuitry would require a period of about 0.83 second to raise the bus to 43 volts. Thus for the first setup situation in this paragraph the trip period is one second. The second setup situation would require a 0.83-second period for trip.

---

* Normal bench test and description of all routine setup procedures are described in ORNL Central Files no. *56-5-30*, section P.

Conclusions

From these examples it is apparent that the actual trip power can vary over a significant range of reactor power. However, the highest power which the system could allow under any combination of circumstances (except failure of all channels) is determined by the situation present if only one channel receives the level information. Since this situation can be simulated during the setup procedure, the ultimate trip point can be specified and becomes an essential part of the setup procedure.

Appendix. Simulated System

Measurements of system interaction were made on a simulated system of four identical sigma amplifiers as shown in Fig. 8. Also, since the clamping currents will flow through the diode and the driving output circuit, each sigma amplifier was supplied by a cathode follower exactly as done in the actual system.

The input and output connections were made in ways to allow complete versatility of interconnection scheme. All voltages were read within 1/4 volt and corrected by a 0.25% Rawson Polyranger Meter. The readings on the sigma bus where loading was being observed were made on the Radio Corporation of America Voltohmyst. All other readings were made by accurately calibrated panel meters.

An Integrated Mobile Microwave Communications System for the Massachusetts Turnpike

RALPH F. LOWE
ASSOCIATE MEMBER AIEE

A COMMUNICATIONS system was conceived and designed which would meet the special requirements of modern toll road operations simply and within reasonable costs.

The Massachusetts Turnpike Authority had requirements for the following services:

1. Telephone service between all maintenance centers and administrative headquarters.
2. Telephone and teletype service between all police barracks and administrative headquarters.
3. Vhf (very-high-frequency) mobile communications:
    a. between cars
    b. between central dispatch and cars
    c. between central dispatch and interchanges
    d. between interchanges and cars
    e. between auxiliary dispatch points and cars or interchanges

An integrated vhf mobile-microwave system, which would meet these requirements, was installed by the General Electric Company. Fig. 1 is a map of the toll road showing the location of microwave stations and the manner in which they are interconnected.

Off-turnpike vhf base station sites were selected to provide the desired coverage of the road and its environs. These sites are on principal hills commanding a good view of the rolling terrain through which most of the Turnpike winds.

The microwave system links each base station with maintenance centers, police barracks, and administrative headquarters located in the heart of down town Boston.

Chicopee Falls is the central dispatch point and all vhf communication is relayed there via microwave. Here, dispatchers monitor all traffic and can transfer control of the system to any of the auxiliary control points at maintenance areas, police barracks, and administrative headquarters. During the day, two operators split the system; one acts as a dispatcher for the western half of the Turnpike; and one the eastern half.

The present vhf traffic load totals about 17,000 calls per month, or one call every $2^1/_2$ minutes. This will increase in the summer months with increased vehicular traffic.

In addition to the vhf system, separate microwave channels provide telephone service for maintenance, police, and administrative personnel. A high-speed party-line teletype loop was installed for the Turnpike police.

Vhf System

The vhf system layout is shown in Fig. 2. Each base station and control

point circuit is brought into the control console at Chicopee Falls on a separate microwave voice channel. Since a single 150-mc (megacycle) vhf frequency pair is shared by police, maintenance services, and administrators, flexibility is a prerequisite of the system. Selective calling of mobiles and interchanges, individual base station control, and a unique control console are combined to provide optimum performance.

Control Console

Fig. 3 is a simplified block diagram of a portion of the control console (only the western circuits are shown). The console contains three voice channels and two operating positions which can be seen in Fig. 4. Each of the vhf base station and control point circuits are connected in multiple to the party circuit and the operators station selector and connector banks shown in their home positions.

The system operates full duplex push-to-talk so that the control circuits, as well as the audio pairs are patched through the control console. Under quiescent conditions, circuits are connected to the party channel through the voting panel, as shown in Fig. 3. This unit serves as a base station selector. When an incoming call from a mobile is received on more than one base station receiver, only one signal is applied to the party channel.

The signal received on the party channel is retransmitted from all base stations and received at all control points. The dispatcher, after making an initial contact, may, at his discretion, transfer the call to channel 1 and free the party channel for other traffic. This is accomplished by the rotary selector and connector moving to the desired station position under the control of one of the push buttons in the vertical rows on either side of the operating position shown in Fig. 5. The disabling contacts open, removing the circuit from the party channel.

Fig. 6 shows the manner in which two vhf circuits may be interconnected through one of the control console channels. Operation of the station push button $S1$ starts relay $K1$ stepping through its interrupter contacts IC until the contact grounded through $S1$ is reached. The disabling relay associated with the position operates, disconnecting

the station circuits from the party channel. Each level of *K*1 connects its associated circuits through the console channel. *S*2 operates the selector switch *K*2 in the same manner and both vhf circuits are connected together. At the completion of the call, the operator must return the selector and connector switches to their home positions by depressing the associated push buttons.

The disabling relays may also be controlled from switches located between the operating positions on the control console, as well as automatically by the selector and connector switches. This feature enables the operator to disconnect a base station from the system in the event that it interferes with normal operations.

A 3-channel tape recorder is provided to keep a record of all traffic carried on any of the console channels. The recorder is started each time a channel is keyed and can record three simultaneous conversations.

BASE STATIONS

Fifty-watt base stations are normally connected directly into a microwave channel but may be switched to operate as an independent mobile repeater. When an incoming signal energizes the carrier operated relay, a voting sequence is started which delays the keying of the microwave channel for a short time. The duration of the delay is inversely proportional to the strength of the incoming signal, the maximum time being about 400 milliseconds, and occurring on the weakest signals.

Generally, two base stations receiving a signal from the same mobile will key their associated microwave channels at slightly different times. The first signal received by the console is selected by the voting panel and any subsequent signals are muted.

Corner reflectors were selected as base station transmitting antennas because of their high front-to-back ratio and they were oriented to minimize phasing areas on the Turnpike.

SELECTIVE CALLING

Mobile and interchange receivers are muted unless the transmission is preceded by a short audio tone burst of the proper frequency.

The dispatchers at the control console can select any of the following groups:

1. Police
2. Maintenance
3. Interchanges
4. Individual administrators
5. All call

If the circuit is being used for police traffic, the mobile receiver in any other group will emit a busy tone when the operator removes the microphone from its hook switch.

INTERCHANGES

Each interchange is equipped with a fixed mobile-type station located in the utility building. There is an extension circuit so that calls can be taken in the central toll booth on a flush wall-mounted speaker and microphone combination.

Microwave System

The microwave system is comprised of 15 stations separated an average distance

of 10 miles. The location of all stations was dictated by the communications requirements and vhf coverage.

A 2,000-mc time division microwave provides almost instantaneous selection and control of base stations by using the channel pulse as the signalling medium. Audio signals are transmitted by position modulation of the channel pulse.[1,2]

The antenna systems were designed to provide path margins which would yield an overall system propagation reliability of 99.6% for the worst month.[3]

Standby radio-frequency equipment is provided on all mainline circuits and an alarm channel provides an indication at Chicopee Falls of the condition of each station. A party line service channel telephone is located at each station to facilitate microwave and vhf maintenance.

Fig. 7 shows the microwave channels exclusive of the vhf channels.

Telephone Channels

The telephone channels are "party line" with dial selective ringing of all parties. Dial pulses are transmitted to all microwave stations by keying the channel pulse in accordance with the digits dialed. All selective ringing units follow the dialing but only one responds by ringing the extension dialed.

The selective ringing units installed on the administration telephone channel provide an additional feature, that of lockout and busy signal to all other parties when the circuit is in use.

Teletype Channel

The police teletype channel is a party channel linking teletype machines at all police barracks and the administrative headquarters in Boston. Teletype signals are transmitted over microwave by keying the channel pulse on and off. This method of transmission, while requiring a voice channel, offers increased reliability through simplicity of equipment and a high-speed keying circuit which can operate even under adverse circuit noise.

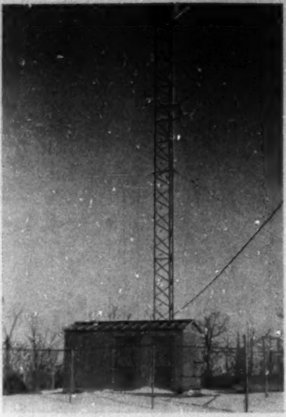

Fig. 8. Off-turnpike installation at Richmond Road

The teletype machines operate half duplex in a standard teletype loop which is closed at the Boston terminal. A message typed on any machine is received on the same machine via the loop.

Installations

Fig. 8 shows the off-turnpike installation at Richmond Road. Stand-by power is provided by a 5-kva air-cooled liquid petroleum-fueled engine generator installed in a separate room.

For economy reasons, guyed towers were used wherever possible. Tower-mounted parabolic antennas are connected to the microwave via semiflexible, pressurized transmission lines. The complete installation, including the construction of access roads, was supervised by the radio equipment manufacturer.

The Turnpike Authority provided space and stand-by power for the communications equipment at maintenance centers and police barracks. At Chicopee Falls, the vhf switching equipment is located in the radio room, a short distance from the control console in the communications center.

Conclusions

By utilizing standard microwave and vhf circuits and building all the complexity into the control console, maximum equipment reliability has been achieved.

Selective calling of vhf units minimizes disturbances to Turnpike operational personnel by eliminating from their receivers, those calls which do not concern them.

By having one manufacturer supply both mobile and microwave equipment, complete system responsibility rests in the hands of one party, a major asset to the customer in dealing with the contractor.

Discussion

Paul C. Shedd (Newark College of Engineering, Newark, N. J.): This paper represents an excellent example of how special enterprises in modern communications can be specifically tailored and designed to meet situations which will not occur again in the same specific form.

A large number of different requirements and conditions are provided for with a minimum amount of fuss, and great flexibility is obtained, by combining standard circuits in a carefully developed plan.

Although the system extends practically across the state of Massachusetts between east and west, the most complex components of the control are sharply concentrated in a single location. This is a great aid to equipment reliability and ease of maintenance.

Work of this nature will undoubtedly become of steadily increasing importance as conditions of increasing complexity present themselves in our expanding economy. It is another indication that our technology is getting ready to meet new situations.

W. J. Kessler (University of Florida, Gainesville, Fla.): It is indeed encouraging to note that each new integrated vhf-microwave communications system constructed for turnpike use constitutes in one way or another a distinct improvement over its predecessors. The Massachusetts Turnpike system as described by the author is graced by at least two noteworthy features. They are:

1. The off-turnpike location of the vhf base stations to take advantage of the terrain in improving coverage not only along the Turnpike but the Turnpike environs as well, that is; the important feeder roads as well. This is a factor which has been overlooked in most of the earlier turnpike systems. This feature obviously requires more extensive microwave facilities but this fact serves to illustrate again the simple axiom that one rarely achieves a truly worthwhile result for nothing!

2. The use of a single vhf frequency pair

for police, maintenance, and administrative functions. It appears that this feature—which is certainly a meritorious one from the standpoint of vhf frequency conservation—is practical because of the use of selective tone signalling and the use of busy-channel indication in all mobile units when the police vhf channel is in use. Should this scheme prove fully practical over the long haul, it is a feature which is certainly worthy of consideration by the designers of future systems.

The author has referred briefly to the use of corner reflectors with high front-to-back ratios at the vhf base stations oriented to minimize phasing-area problems. Such vhf-overlap areas which are characterized by increased hash and noise in the mobile units, is one of the more formidable problems always encountered with integrated vhf-microwave turnpike systems for which no fool-proof solution has yet been found.

In fact this problem alone is important enough to be the topic of another paper. Concluding, one cannot help but speculate whether it might be practical to utilize the rolling terrain, which is typical of the area through which most of the Massachusetts Turnpike winds, to ameliorate further this phase-area problem by locating the vhf base stations and adjusting the effective radiated powers so that the high-elevation spots of the terrain along the Turnpike proper would serve to isolate or separate the coverage areas of adjacent base stations

The author points out that the teletype signals are transmitted by keying the channel pulse off and on. I can well appreciate the simplicity of this scheme but must admit that I do not grasp completely the reasons for the high noise-immunity properties suggested in the paper, since it appears that the full voice channel is not effectively utilized for the transmission of information-bearing signals. Unless of course the amplitude-modulation spectrum of the channel pulse under high-speed keying conditions extends throughout the entire voice channel. Perhaps this point will be clarified during the presentation.

Ralph F. Lowe: The discussion by Paul Shedd brings out an important point, that of the careful planning which must go into the engineering of a system of this type.

Because all the radio equipment was from one manufacturer, close co-operation was easily maintained between microwave and mobile application engineers.

The field project engineer supervised most of the application work before moving his residence to the field where he co-ordinated the construction of the Turnpike buildings in which radio equipment would be installed.

Off-turnpike buildings, roads, and towers were constructed during the manufacture and test of the radio equipment and the installation was complete in less than one year from the date of the contract.

Professor Kessler's speculation regarding the effect of terrain on phasing areas undoubtedly is the explanation for the short overlap areas observed on the Massachusetts Turnpike. Another factor, which was brought out during the presentation, is the affect of the relative phase of the audio signals modulating the interferring transmitters. By using individual microwave channels to connect the base stations the phase shift difference between them is minimized and no special correcting networks are required.

The teletype circuit actually uses a binary pulse code modulation system which should provide approximately 3 db signal-to-noise improvement over a pulse position modulation system.

This can be explained by the fact that the intrinsic noise shows up as incidental time modulation of the channel pulse due to the action of the clippers and reshapers following the receiver. The signaling circuit depends only upon the presence of a channel pulse in the gate and not its position in the gate or the fact that it may be changing position due to modulation or noise. In addition, the circuit need only detect a full-on or -off (binary) condition and full noise (no signal) does not have sufficient duty cycle to operate the relays.

Experience indicates that circuit noise causes more teletype "hits" when using frequency shift subcarriers than when using pulse code modulation.

Even though the amplitude-modulation spectrum of the teletype signal does not extend very far over the voice channel, the space is unavailable for other circuits.

Tropospheric-Scatter System Design

LEANG P. YEH
NONMEMBER AIEE

THIS paper attempts to present a comprehensive procedure, from an approach partly experimental and partly theoretical for the design of tropospheric-scatter communication systems, using single side band (SSB) or frequency modulation (FM) and frequency division multiplex (FDM).

Since the art is still young, controversial views and discrepancies are found elsewhere in the literature. But from the system design point of view, some means must be provided to determine the parameters and to predict fairly well the performance from such parameters. This paper is written, therefore, with this goal in mind.

The methods as given are by no means the absolute choice. It is hoped that by the same approach, a unique method could be obtained and agreed upon someday by all concerned.

System Design

System design for an FDM operation is based on the required signal-to-total-noise power ratio per channel at the receiver output.

The total noise in any FDM radio system has two origins:

1. Intermodulation noise due to nonlinearity of the system components.
2. Other noises such as thermal noise inherent in the receiver, and external noises such as cosmic noise and man-made noise received by the antenna.

The treatment of intermodulation noise in system design is discussed in a separate paper under preparation. Only the second type of noise is covered here. In the region of 300 to 4,000 megacycles or above, extensively used in tropospheric scattering, the thermal noise of the receiver predominates at isolated locations where the terminals are likely to be located. This second type of noise will, therefore, consist of thermal noise only.

Table I outlines the general procedure for the design of a tropospheric-scatter system, based on the minimum usable signal-to-thermal-noise power ratio per channel at the receiver output.

MINIMUM-CHANNEL SIGNAL-TO-THERMAL NOISE POWER RATIO FOR USABLE COMMUNICATION

It seems that there is as yet no universal agreement on the minimum usable channel signal-to-noise power ratio. Figures, available for circuits carrying speech, from various sources are given in Table II.

Paper 58-816, recommended by the AIEE Radio Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 12, 1958; made available for printing April 17, 1958.

LEANG P. YEH is with Westinghouse Electric Corporation, Baltimore, Md.

Permission to release the information in this paper by Westinghouse Electric Corporation is greatly appreciated. The author is also indebted to N. B. Tharp, E. L. Smith, and J. B. Murray for their encouragement, guidance, and helpful suggestions.

K	Boltzmann's constant = 1.38×10^{-23} joules/°K	
T	Temperature = 290°K	
B_{if}	IF bandwidth = f	IF bandwidth = $2(F_d + 2f)$

*dmi - path length in statute miles f_{mc} - carrier frequency in mcps

D - antenna aperture in ft λ - wavelength in ft

4. Fading Margin and System Reliability

$$\text{Fading margin in db} = \text{Med.}[\frac{P_R}{N_A}] - \min[\frac{P_R}{N_A}] + G_c$$

G_c = combiner over selector diversity gain

The System reliability can be read off from long-term instantaneous signal distributions (probability combination of short-term and long-term distributions).

Table II. Minimum Usable Signal-to-Thermal-Noise Power Ratio

Source	Average-Speech-to-Average-Noise Ratio, Db	Peak-Speech-to-Average-Noise Ratio, Db	Remarks
Barsis[3]	11		88% reliability
Morrow[4]	15	25*	90% articulation without compandor
Morrow[4]	10	20*	90% articulation with compandor
C.C.I.R.[5]	15	21†	90% intelligibility without compandor

* Peak speech is assumed to be 10 db above average speech.

† Peak speech is assumed to be 6 db above average speech.

It is understood that these figures are also good for other kinds of signals, except perhaps facsimile.

It is suggested that a minimum of 15-db (decibel) channel average-speech-to-average-thermal-noise power ratio (without compandor) is considered usable.

Since the channel signal-to-thermal-noise power ratio is usually specified for 0-dbm (decibels referred to one milliwatt) test tone, the minimum usable ratio becomes 25 db on this basis, if the average speech level is assumed to be about −10 dbm.[6]

MINIMUM CARRIER-TO-THERMAL-NOISE POWER RATIO FOR USABLE COMMUNICATION

Once the minimum-channel signal-to-noise power ratio for usable communication is established, the corresponding minimum carrier-to-thermal-noise power ratio could be obtained if the number of multiplex channels and the modulation techniques are known.

For FM systems, there is also the threshold effect. The average-carrier-to-average-thermal-noise power ratio at practical threshold has been established as 10 db.

Therefore, both the minimum (S_0/N_0) and threshold (P_R/N_A) should be considered in designing FM systems. From

Vol.
Pt. 1
1958

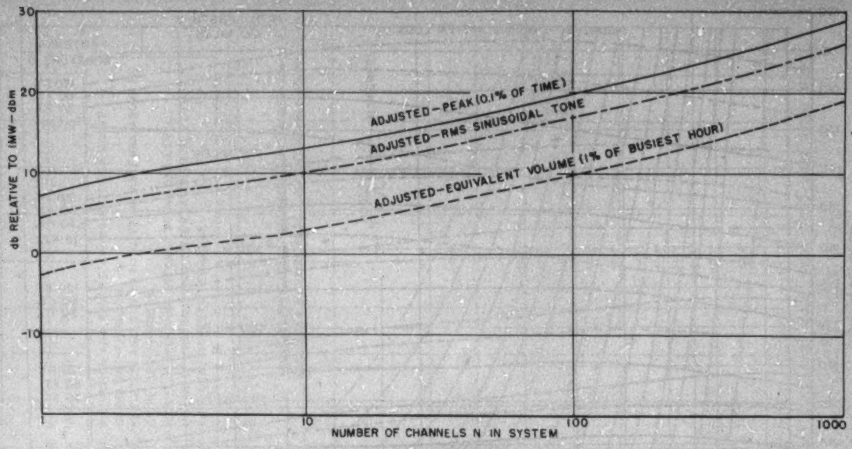

Fig. 1. Channel loading factor

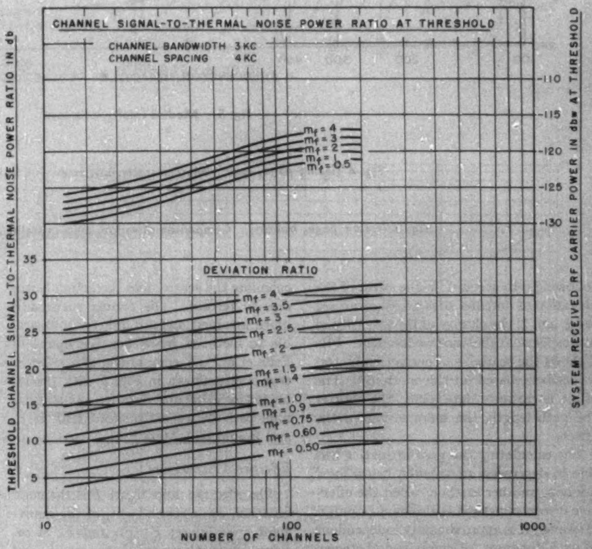

Fig. 2. Threshold channel signal-to-thermal-noise power ratio

them the deviation ratio is usually determined.

Fig. 1 gives the channel loading factor (adjusted Holbrook and Dixon[7]) and Fig. 2 gives the channel signal-to-thermal-noise power ratio versus number of channels at various deviation ratios.

MEDIAN CARRIER-TO-THERMAL-NOISE POWER RATIO

The median received carrier power is the difference between the transmitter power and the median total system loss. The thermal-noise power may be calculated if both the noise figure and i-f (intermediate-frequency) bandwidth of the receiver are known.

Median Total System Loss

Fig. 3 gives the median total system loss for smooth-earth geometry. It is plotted with total loss versus frequency, path distance, and antenna aperture. It may be used to determine the optimum frequency, which is the one that gives minimum loss.

Terrain Effect

Since the majority of experimental data used for deriving the median total system loss was obtained from scatter geometry, fairly similar to smooth earth, the effect of terrain must be considered in dealing with nonspherical-earth scatter geometry.

The effect of terrain, defined as scatter-loss correction factor, could be a loss or gain, depending on whether the antenna is elevated or depressed in elevation relative to the local horizon. (This is different from the so-called radio horizon; see Fig. 5.) It is also statistical in nature, but the median value is of importance. Several methods have been advocated to calculate the median value. Kurihara's method[1] is adopted because it takes the

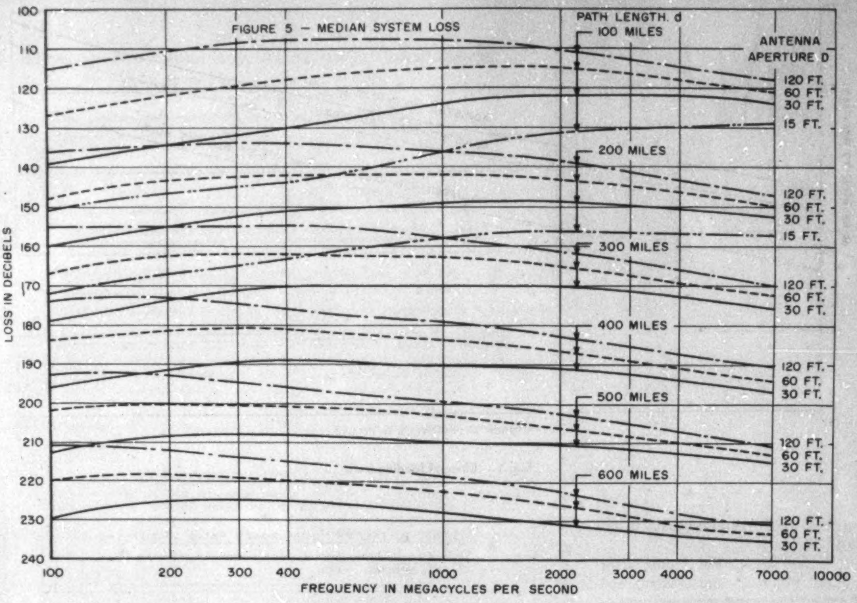

Fig. 3. Median total system loss

Fig. 4 (facing page, top). Median scatter-loss correction factor due to terrain

Fig. 5 (facing page, bottom). Comparison of various median scatter-loss correction factors

following into account: 1. the effect of the elevation of antenna sites above mean sea level, and 2. the change of the intensity of atmospheric turbulence with height. Fig. 4 shows the scatter-loss correction factor[8] in decibels, based on this method.[8] The effect is distance dependent, the shorter the path length, the more serious is the effect.

For calculating the gain in scatter loss due to depression of antenna below local horizon, another method called the effective distance method is also very popular. However, it is approximately independent of path distance. A comparison between this method and Kurihara's is shown in Fig. 5.

The effective distance method cannot be applied to cases when the antennas are elevated above local horizons to clear obstacles along the path. However, there are two other methods advocated by Norton, et al.,[9] and Friis, et al.[10] to calculate the scatter-loss correction factor due to terrain. The former method is more involved and not directly comparable to methods by either Kurihara[1] or Friis et al.[10] A comparison of the latter two is also shown in Fig. 5 with the reported experimental data for 188-statute-mile path between Crawford Hill, N.J., and Round Hill, Mass.[11]

Effective Noise Figure

The effective noise figure F is the combination, on a power basis, of the equivalent noise figures F_r, F_c, and F_n of receiver thermal noise, cosmic noise, and man-made noise respectively. In the event that the actual value is not available, approximate values may be obtained from Fig. 6.

FADING DISTRIBUTION

Heretofore, the fading is arbitrarily subdivided into two components because of their natures, fast and slow, in order to facilitate the mathematical analysis. The slow fading is believed to be caused by the change in tropospheric conditions, such as the change of index of retraction of the atmosphere and the fast fading by multipath transmissions.

Practically, the two are inseparable because the signal received is always the combination of both, which may be called the instantaneous signal. Therefore, if the instantaneous signal distributions of the hour, the day, the month, or the year are known, the system reliability for a certain fading allowance could be predicted fairly precisely for whatever period is intended.

The instantaneous signal distributions could be obtained experimentally. If an experimental curve is not available, the probability combination of short-term and long-term fading distributions may be used instead.

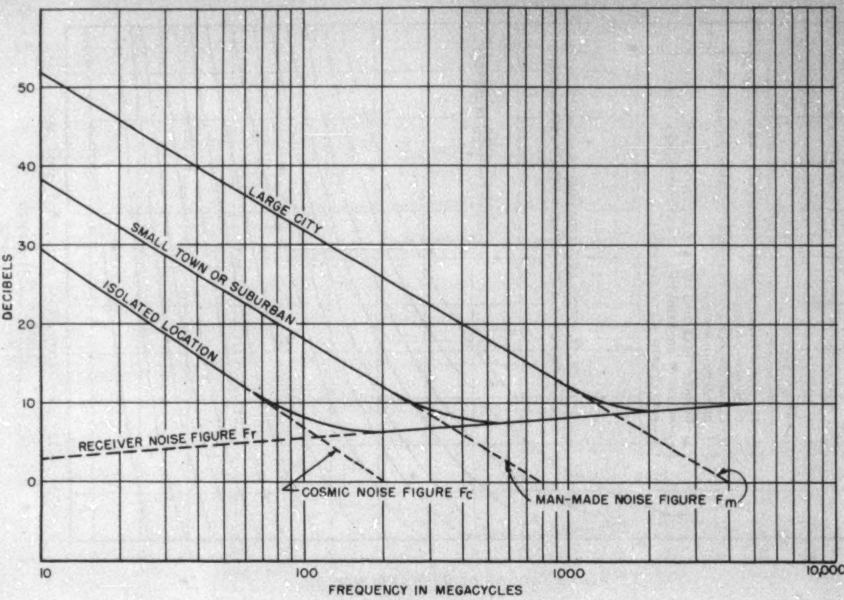

Fig. 6. Effective noise figure

Fig. 7 (facing page, top). Long-term fading distribution

Fig. 8 (facing page, bottom). Short-term fading distribution

Conventionally, it has long been assumed that for nondiversity operation the short-term fading distribution, e.g., within the hour, is Rayleighan; and that between hours, the long-term fading distribution (distribution of hourly medians) is Gaussian, with different standard deviations for various path lengths. However, work[12] recently done by Westinghouse has proved that the sampling period for short-term Rayleighan Distribution fast fading should be established as one minute and that the long-term Gaussian distribution slow-fading median signal level should be more conveniently specified on a minutely basis.

The minutely median, according to the analysis of limited amount of 1-minute totalizer recordings,[12] does change from minute to minute. The distribution also approaches Gaussian. It is believed that if enough data are taken on a long-term basis (monthly or yearly), minutely median distribution should not be much different from the hourly median distribution.

Pending the establishment of the long-term minutely median distributions, a set of long-term probability-combined fading distributions or long-term instantaneous signal distribution—using long-term hourly median distributions as shown in Fig. 7, short-term distributions for nondiversity, and selector diversity operations as shown in Fig. 8—is shown in Fig. 9. This set of curves is used to determine the reliability of the system. It can be seen that there is a diversity median gain of about 2 db and 4 db for order of diversity $(n)=2$ or 4 respectively. For combiner or linear adder diversity operation, the additional gains shown in Table III, according to Altman and Sichak,[13] should be added.

Westinghouse has analyzed 293 hours of the data between January and February 1957 on the Baltimore, Md., and Verona, N.Y., link operating at 960 megacycles over a path length of 268 miles. The data were obtained through the courtesy of Rome Air Development Center. The experimental instantaneous signal distributions as shown in Fig. 10 fit well to the combined curve calculated by the foregoing method. It is expected that a better fit would be obtained if a monthly minutely median distribution for the same month were available to calculate the combined curve. Experimental hourly median distribution is also shown for comparison. It is interesting to note that the monthly median obtained from either the monthly-hourly median distribution, or the monthly instantaneous signal distribution is exactly the same as predicted.

Deviation of experimental instantaneous signal distribution from calculations at the strong signal region indicates that there is signal enhancement due to external effects such as aircraft, trapping, or ducting, etc.

SYSTEM RELIABILITY

The difference between the median and minimum (P_R/N_A) is the fading margin. System reliability can be read off from the curves in Fig. 9. For combiner diversity system, the combiner over selector diversity gain G_c should be added.

SAMPLE DESIGN

A sample design is shown in Table IV. A comparison between SSB and FM systems may be summarized as follows:

1. System reliability—For the same average transmitted power single side-band systems have higher reliability.

2. Threshold effect—FM system can only be operated above the practical threshold, below threshold it fails completely. In SSB system, there is no such effect.

3. I-f bandwidth—FM systems require wider i-f bandwidth. In order to accommodate the wide band, it is sometimes necessary to use larger antennas. In some instances because of the limitation of the usable bandwidth in tropospheric-scatter transmission, wide bandwidth simply cannot be accommodated.

4. Multipath transmissions—For multichannel operation, multipath transmission will cause frequency selective fading in SSB systems which can be overcome by the use of multiple-pilot amplitude regulators. With FM, the effects of frequency selective fading are complex. Both intermodulation noise and channel level instabilities can be produced. The former puts another limitation on the usable bandwidth.

5. Spectrum economy—As shown in the sample design, for the same base-band frequency, SSB required far less spectrum space than FM (48 kc versus 600 kc).

COMPARISON OF PREDICTED RECEIVED SIGNAL LEVEL BY PRESENT METHOD WITH EXPERIMENTAL DATA

A number of available data on received signal level from experimental links with the calculated predicted values by the present method are tabulated in Table V.

Radar Interference to Microwave Communication Services

R. D. CAMPBELL
MEMBER AIEE

IT IS THE PURPOSE of this paper to discuss the growing problem of interference between radar transmitters and microwave communication systems and the urgent need for the application of measures to enable these two radio services to coexist in the microwave spectrum. The problem basically is a difficult one since the radar transmitters use power outputs measured in megawatts, whereas the microwave transmitters normally use powers of 10 watts or less. The Bell System became aware of this problem as the result of a number of cases of interference to its microwave communication systems from radar operations. Two general types of interference are involved: 1. that resulting from the operation of radars directly on fundamental frequencies used for communication services, and 2. that due to the generation and radiation by the radars of spurious frequencies including harmonics which fall in bands and on frequencies used for communication services. The former type of interference can be eliminated through control of the frequency assignments for both radar and communication purposes. The latter type, however, is not so readily disposed of.

While a number of cases of radar interference have been experienced over the years since World War II, it was not until late 1954 that the seriousness of the problem was fully recognized in the telephone industry. During that year, severe radar interference was experienced to a *TD-2* microwave system operated by the Pacific Telephone and Telegraph Company for transmitting television signals from Los Angeles to Las Vegas, Calif.

The *TD-2* microwave system, which was developed by Bell Telephone Laboratories, was first placed in operation between New York City and Chicago, Ill., in September 1950. It operates in the frequency range 3,700–4,200 mc (megacycles) and is designed to handle from 1 to 12 broad-band channels, 6 in each direction of transmission along a route.

One of the frequency plans extensively used for the *TD-2* system is that shown in Fig. 1. As indicated, in a given direction from a repeater station the receiving frequencies are spaced by 80 mc and are centered between the transmitting frequencies which are also 80 mc apart. For branch routes intersecting at small angles, frequencies in between those shown are used to avoid interference. Ordinarily four antennas are employed at each repeater station, one pointed each way for transmitting and one each way for receiving. On some light routes a single antenna pointed each way may be used for both transmission and reception.

The *TD-2* system employs frequency modulation with a power output of only 1/2 watt for each broad-band channel. Two such broad-band channels, one for each direction of transmission, normally handle up to 600 telephone circuits or two television signals.

The route from Los Angeles to Las Vegas on which the radar interference was experienced was used for 1-way transmission on the frequencies 3,790 and 3,830 mc. Fig. 2 shows the location of this route. The interfering radar signals were entering the receiving antenna of the repeater at Strawberry Peak together with the desired signals on 3,700 mc. The radar signals were traced to spurious radiations of an *S*-band acquisition radar located in Los Angeles some 60 miles away.

As a result of this experience Bell Laboratories undertook an investigation of the causes of radar interference and means for avoiding or minimizing such interference. This effort was directed along the following lines:

1. Determination of the effect of radar-type emissions on the *TD-2* microwave system.
2. Study of the radiated frequency spectrum of certain high-power radars in use or planned for use by the military.
3. Investigation of means of suppressing the spurious and harmonic radiations from the radar emissions.

Effect of Radar-Type Signals on the TD-2 System

The first of these studies was carried out in the Laboratories by injecting varying known amounts of pulsed radar-type signals into the crystal mixer in the head end of a *TD-2* receiver, together with a simulated multichannel telephone signal corresponding to that normally received over an average microwave path. The results of these tests are illustrated in Fig. 3, where it is seen that as the peak value of the pulsed radar signal approaches the peak value of the desired signal the interfering telephone circuit noise rises very rapidly from negligible amounts for carrier-to-interference ratios of 5 db (decibels) or more, to intolerable amounts for carrier-to-interference ratios of −5 db or less. For the case of television, it was found that interference would result from radar signals 25 db weaker than those which cause interference to multiplex telephone circuits. The interference level for circuits carrying SAGE data signals is estimated to be about the same as for telephone. Although the tests just referred to were conducted on a *TD-2* receiver, field tests with other types of

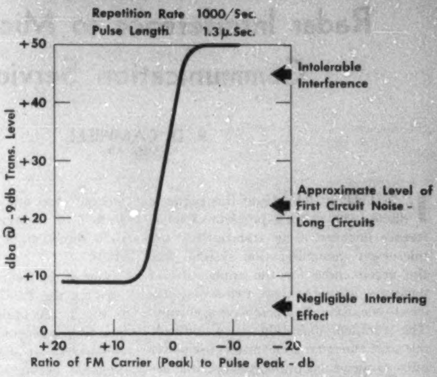

Fig. 3 (right). Effect of radio-frequency pulse interference on the TD-2 system

microwave equipment indicate similar effects.

Fig. 4 shows the effect of radar interference on a television picture. The separation between the dashes of interference seen in this picture depends on the radar repetition rate, and the length of each dash depends on the radar pulse length. In a telephone circuit the interference is evidenced by a rough buzzing noise.

Extra Band Radiation Characteristics of Radars

The Bell Laboratories investigation of radar frequency spectrum characteristics was carried out with the aid of a Polarad receiver with four radio-frequency heads mounted in a truck, with calibrated horns on the roof. The receiving equipment was capable of adjustment to any frequency in the range 2,100 to 11,260 mc. Fig. 5 shows the test truck. Attenuators were provided to prevent overloading the receiver with strong radar signals. The truck was also equipped with an oscilloscope to observe the signals being measured and a pulse generator which was used to simulate the radar signals and determine their amplitude by the substitution method. Through co-operative arrangements with the Army, the Navy and the Air Force, measurements using this equipment have been made on a number of radars commonly in use or under construction. The radars studied included nine different types, one using a klystron and the others using magnetrons as the frequency-generating source. The power output at the fundamental frequencies ranged from 0.14 to 5.0 megawatts. All of the units tested were found to be radiating spurious products of very substantial magnitude. The results of these tests are shown in the mass plot of Fig. 6, on which each harmonic and spurious product is shown as a point indicating its magnitude or power as ordinate versus the ratio of its measured frequency to the fundamental frequency of the radar as abscissa. As indicated, the spurious emissions range up to as much as 93 dbm (decibels referred to 1 milliwatt) effective radiated power, while many of the products observed had powers ranging from 40 to 70 dbm. The term "effective radiated power" (ERP) is used to express the peak power radiated by the radar including the gain of the radar antenna at the frequency in question. By way of comparison, it is interesting to note that the *TD-2* system has an ERP of only 66 dbm (0.5 watt power with a 39-db antenna gain). The radar harmonics shift up and down in frequency as the fundamental is changed. Likewise, some of the spurious outputs vary with magnetron tuning; others are fixed, or they vary only slightly. The latter probably depend on some geometry of the magnetron. All of the radars tested emitted extra band products which fell into one or more of the frequency bands used for common carrier services as well as in other bands. When these products fall directly on the communication frequencies being used, receiver selectivity affords no protection and the only means of avoiding interference is by antenna directivity; shielding by hills, trees, buildings, or other obstructions; and by physical separation of the radars from the communication receivers. Fortunately, most *TD-2* stations employ well shielded horn reflector or delay lens antennas, the directive characteristics of which are shown in Fig. 7. While such antennas greatly minimize the possibilities of interference from radars not directly in line with the receiving path, they are not capable of completely protecting against spurious emissions of powerful radars even though located "off-beam" at considerable distances.

Magnitude of Problem

Based on the previously mentioned measurements of the radar radiation

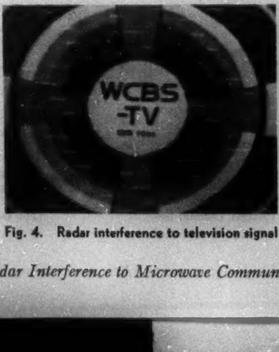

Fig. 4. Radar interference to television signal

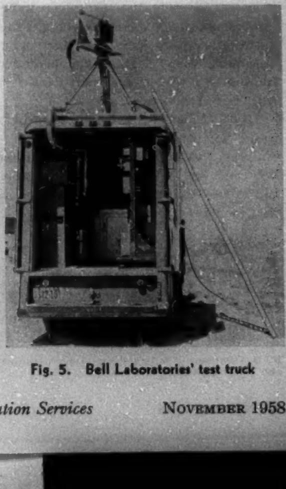

Fig. 5. Bell Laboratories' test truck

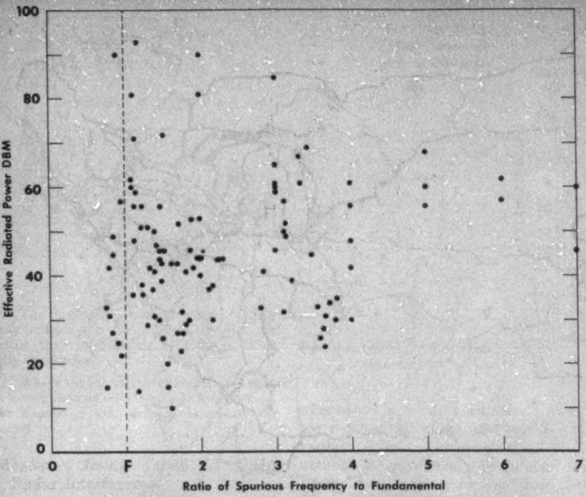

Fig. 6. Distribution of measured spurious and harmonic products of nine radars

characteristics, and their interfering effect on the *TD-2* system, it is possible to estimate whether interference will result from a radar at any specific location. Fig. 8 gives a graphical illustration of the extent of the interference areas that may be involved. This is a polar diagram centered on a *TD-2* station receiving signals over a nominal 30-mile path from a *TD-2* transmitter at point *T*. A radar transmitter emitting a spurious signal of 45-dbm ERP on a receiving channel being used for television reception may cause interference if it is located within the shaded area. The same area also applies to the case of a radar transmitter emitting a spurious signal of 70-dbm ERP on a receiving channel being used for telephone operations. As indicated in Fig. 6 many of the radars have spurious products as big or bigger than those assumed. The shaded area was calculated on the assumption that line-of-sight transmission exists for distances up to 30 miles with beyond-the-horizon smooth-earth transmission losses applying at greater distances. Fading of the desired signal of 30 db was also used in these calculations, since the *TD-2* system is designed to provide service in the presence of fades of this magnitude.

Considering the very appreciable size of the interference area indicated by Fig. 8, and the extensive use being made of microwave radio to provide the nation's communication needs, the reason for concern about the radar interference problem becomes apparent. Of all the microwave communication systems in service today, the Bell System alone operates more than 30,000 route miles consisting of some 1,300 individual stations scattered throughout the country. These facilities are used to provide 62,000 miles of intercity television circuits and about 13 million miles of long-distance telephone circuits. These circuits, which have been installed in a period of only 8 years comprise 80% of all the intercity video and about 25% of all long-distance telephone circuit mileage in the Bell System plant.

In addition to providing long-distance telephone and television services, these circuits are used for important industrial and governmental private-line services. The bulk of these circuits are provided

Fig. 9. Broad-band microwave radio relay systems: Bell and connecting routes

by broad-band microwave facilities, mostly *TD-2*, which operates in the 4,000-mc common-carrier frequency band. Fig. 9 shows the widespread extent of this broad-band microwave network. In addition to the routes shown here, the Bell Companies operate a large number of short-haul narrow-band microwave systems carrying up to a few dozen circuits each. These systems operate in the 890- to 940- and the 5,925- to 6,425-mc bands. Extensive use of the latter band for long-haul heavy route service is also planned by use of the *TH* microwave system which had been developed by Bell Laboratories. This system can be used to greatly increase the capacity of existing *TD-2* microwave routes or for the establishment of new routes. The Laboratories have also developed a new microwave system known as the *TJ* system which is being introduced into the plant this year. This system operates in the common carrier band 10,700 to 11,700 mc and will be used primarily for short-haul telephone and television services.

Considering the magnitude of the microwave network facilities and the extensive use being made of radar it is surprising that only a relatively small number of interference cases due to spurious radar emissions have been reported to date. This is believed due to the following principal factors:

1. In many critical locations the high-powered radars which are planned for use have not yet been placed in operation. As they go into service many severe cases are expected.

2. The radar may be operated on frequencies which have not resulted in spurious emissions falling directly on channels being used at exposed microwave stations. (Military considerations make frequency changes desirable.)

3. Many of the microwave receiving sites are shielded from the radars by hills, trees, or man-made obstructions.

4. On lightly loaded routes the receiving frequencies used may be selected so as to avoid the unwanted radar products. This is not possible on heavy routes.

5. Some of the operating people may not be fully aware of the nature of radar interference and may have failed to report it. Radar interference causes noise on telephone circuits, and pigeons (flying spots on picture tubes) or other effects on television signals similar to effects which sometimes arise from other causes.

6. The radar or the communication facility may be used only part of the time, with the result that interference is avoided or is only intermittent.

7. Where the interference level is such that it is troublesome only during fading periods, the chance of identification is greatly reduced.

Measures Being Taken to Avoid Radar Interference

The question naturally arises as to whether radar interference to microwave systems might be minimized by increasing the power used by the communication systems. Consideration of this possibility indicates that it would not provide a satisfactory solution. The receiver sensitivities used are generally of the same order of magnitude as those used by radar receivers. To overcome interference from severe exposures to radar spurious emissions would require a terrific increase in the power of present microwave transmitters amounting to about 100 db. Not only would the use of powers such as this be wasteful, and technically and economically impracticable, but it would greatly aggravate the interference problem generally and would be contrary to the established radio principle of using the minimum practicable power for the type of service required.

Fortunately, the government agencies which use radars have recognized the seriousness of the radar interference problem, not only because it may affect Bell System services adversely, but because of its threat to other important microwave radio services including those operated by the military establishments themselves. This awareness of the problem has resulted in close co-ordination between the Bell System and the various governmental agencies in the selection of sites for new microwave communication and radar stations so as to minimize the possibilities of interference.

The problem is particularly severe where microwave communication facilities are required to serve radar sites. Advantage is taken wherever possible of natural or man-made obstructions to shield the microwave receiver from the direct radiation of the radars. Careful consideration is given to the frequencies used in order to avoid, as far as possible, those on which harmonic or other spurious products of the radars may fall. Where such measures fail to provide the necessary protection, it may be necessary to try special shielding of the communication receiving antennas, limitation of the frequency tuning ranges of the radars, or the use of sector blanking of the radars to prevent transmission directly toward the communication receiver.

It is recognized that such measures can be only temporary expedients at best. With the growing use in this country of both microwave communication services and radars, coupled with the trend toward higher powers for radar transmitters, it is obvious that means must be found to suppress radar radiations on frequencies outside the bands in which they are intended to operate, to values which are not likely to cause interference to other services. Such measures will not only give greater freedom in the selection of interference free sites for radar and communication facilities, but will also minimize the problems of mutual interference arising from the operation of large numbers of radars in given geographical areas.

The fact is recognized that it is probably impossible completely to eliminate spurious and harmonic products from the output of radar transmitters, and the question naturally arises as to how much suppression it is necessary to achieve to keep the interfering potentialities of the radars within reasonable bounds. The answer depends, of course, upon the characteristics of the facilities it is desired to protect as well as the power of the radar. Considering the problem of interference to the *TD-2* system, a table, Fig. 10, has been prepared, indicating the maximum effective radiated power that can be tolerated under various conditions from harmonic or spurious radar products falling in the receiving channel of a *TD-2* station. These figures assume an average 30-mile spacing of *TD-2* stations and include an allowance of 30 db for fading. From this table, it is seen that, to allow maximum freedom in the choice of location of radar stations and microwave communication sites, the emission of the radar on frequencies used for communication services should be limited to −35-dbm ERP. As indicated, somewhat greater levels can be tolerated where geographical separation and antenna discrimination permit. To achieve the −35-dbm levels with radars currently in use having spurious emissions of 40- to 70-dbm, ERP, a reduction of some 75 to 105 db is necessary.

Means of Suppressing Spurious Radar Emissions

Recognizing the seriousness of radar interference, the military services have initiated studies in their own organizations and through contracts with manufacturing, engineering, and development organizations seeking a solution to this problem. As part of the effort, Bell Laboratories has undertaken studies of means of suppressing the unwanted radiations from the *M-33* radar. In this work consideration was given to the possibility of suppressing the spurious signals within the magnetron, to the use of pulse-shaping techniques and to the use of a high-power filter in the transmitter output.

These studies indicated that the most practicable approach for the *M-33* was the development of a high-power filter. Investigation of this method has led to the design of a nonreflecting type of filter which preserves the transmitter stability in the mode frequency part of the spectrum.[1] Fig. 11 shows a cross-sectional view of the filter. The complete assembly consists of two identical evacuated filter sections *A*, coupled through two carefully balanced hybrids in such a manner that the transmitted signal entering the input hybrid *B* will follow one of two paths. Signals in the pass band will divide equally through the two filter sections, recombine in the output hybrid *C*, and be transmitted to the antenna through a short section of flexible waveguide *D*. Signals in the stop band will be reflected at the filters, recombined in the input hybrid and be dissipated in the input dummy load *F*. The output dummy load will absorb no power with a perfectly matched system, but it is required to handle reflections and mismatches in the output end of the filter which result from manufacturing tolerances and possible malfunctions in the waveguide assembly.

The electrical characteristics of the filter are shown in Fig. 12. This figure shows an insertion loss of 0.50 to 0.75 db over most of the pass band with an increase to just under 1.0 db at the ends of the band at 3,100 and 3,500 mc. The attenuation increases sharply above the pass band to more than 70 db at 3,700 mc, the lower edge of the band used by the *TD-2* radio relay system. The attenuation remains above 70 db from 3,700 to 3,950 mc and then falls off to a plateau of about 65 db up to at least 4,500 mc. While a single filter of this design will not reduce the *M-33* spurious products sufficiently to meet the −35 objective fully, it will greatly reduce the likelihood of interference from this type of radar.

Conclusions

Continued work on the radar interference problem is necessary if the usefulness of the radio spectrum for general communication purposes is to be preserved. This work divides into two parts: 1. that required for the development of means of suppressing unwanted emissions from existing radars to eliminate interference situations as they arise, and 2. development of improved techniques for the design of new radars which will result in the elimination of, or greatly reduced, spurious products at the source. Just as other interference problems which have seriously threatened to limit the usefulness of the radio spectrum have been overcome, so there is confidence that engineering techniques will be developed to conquer the radar interference problem.

Discussion

Harry R. Meahl (General Electric Company, Schenectady, N. Y.): The data Mr. Campbell has presented should prove useful to all who are interested in personnel safety as well as to communications engineers. Fig. 6, which shows the distribution of measured spurious and harmonic products of nine radars, reveals clearly why both broad-band and tuned monitors are needed at high-powered radar sites.

Some have assumed that both the near and far field patterns of radars may be calculated with enough accuracy for satisfactory application to personnel safety problems.

This article makes it obvious that both spurious and harmonic radiations can be too large to be ignored with impunity. The author is to be commended for achieving brevity together with broad coverage of his subject.

R. D. Campbell: I am very appreciative of the kind remarks made by Mr. Meahl about my paper on radar interference. Fig. 6 does show the need for broad-band and tuned monitors if those responsible for the operation of radars built to present-day standards are to keep track of their radiation characteristics. The indications from such monitors might be used as the basis for making adjustments of the radar equipment to minimize certain interfering products. However, such adjustments would become complicated and impracticable, particularly where a number of microwave receivers are being operated on different frequencies at exposed locations.

It seems obvious that the best solution is that suggested in the paper; i.e., the development of techniques to clean up the radar outputs so that they will not radiate appreciable amounts of energy on harmonic or other spurious frequencies. The output filter described in the paper illustrates one way in which this can be done. If such measures are applied to all radars, the broad-band and tuned monitors would not be needed, the interference problems would be minimized or eliminated, and there would be no hazard to personnel from such products. The personnel hazard from the radar fundamental would still be a major problem, however, as the fundamental is radiated at much higher energy levels than the spurious products.

Automatic Mobile Telephone System

R. P. DIMMER
NONMEMBER AIEE

MOBILE radio-telephone service has been available to the American public since its inauguration in St. Louis in 1946. While this service is quite extensively in use today by mobile subscribers, and to some extent in rural areas, the present system requires an operator to complete the connection between a mobile and land subscriber. This paper covers a development of equipment that will work satisfactorily into present dial telephone equipment. The system has been developed for the telephone section of the Rural Electrification Administration, and was the result of work done in the laboratory since 1946. The pilot system originally was installed in the North Florida telephone company's property in Branford, Fla., and recently was transferred to the same company's exchange in Live Oak, Fla.

It is anticipated that this new equipment will serve rural areas in three ways:

1. By providing telephone service to isolated ranches and farms, island locations, and rural areas that cannot be served by wire lines. This would be classified as "fixed mobile service."
2. By providing mobile subscriber service where it is desired for farm, commercial, or industrial use in automobiles, trucks, boats, and planes.
3. By providing radio-telephone communication between the telephone office and its own mobile units for maintenance and operation.

Some unusual problems are encounted when furnishing automatic dial telephone service to mobile subscribers. When a subscriber makes a conventional call, a d-c loop circuit is completed between his telephone and the central office equipment. This circuit causes a train of events to take place at the telephone equipment which takes over or seizes an idle incoming selector. As long as the subscriber's handset is in an off-hook condition, this circuit is held. When the subscriber dials a number, the circuit is advanced through a network of switches and relays, and eventually to the called party line. In a mobile radio system, a similar loop circuit cannot be maintained because the mobile radio transmitter does not remain operated except when the subscriber is talking. The operating mobile radio transmitter would correspond to the d-c loop circuit of the land subscriber. Consequently, seizure and holding of a line by the mobile subscriber must be locked in for a period of time (2.5 minutes has been found most satisfactory). It is also desirable to permit the mobile subscriber to release this seizure at any time prior to the end of this locked-in period. If his release signal is not received because atmospherics, for example, then the central office control circuits should be automatically released by the timer. If a connection is completed, it is also desirable to remove the release timer from the circuit until at least one party hangs up.

Essentially, this new system permits a regular telephone subscriber to dial any mobile subscriber in a community, or a mobile subscriber can dial any telephone subscriber without the aid of an operator except presently for toll calls. When long-distance toll dialing is in full use, it is expected that this type of service could also blend into this system. It also permits any mobile subscriber to call any other mobile subscriber through the control equipment using the existing telephone reverting call technique or a newer simplified method, which will be described later in this paper.

The primary consideration in the design of the equipment for this system was to make the procedure of making calls as nearly identical to conventional party line land service as possible. The one exception to this plan is the necessity of using a push-to-talk switch at the mobile end. The fixed mobile subscriber would not require this switch, because in this case the transmitting and receiving antennas can be separated by sufficient distance to prevent interaction.

The control equipment between the radio and telephone equipment was designed to connect to any type of automatic telephone line equipment with a conventional party line of a community automatic exchange (CAX) with four wires (two line wires, and two control wires). The present design allows for 20 mobile subscribers on a fully selective basis. The design can be expanded to any number of subscribers on a fully selective ring if desired.

Dial-to-dial mobile telephone service has been kept in obscurity partially because of the problem of charging for such calls. With no operator involved on these calls, it has usually been considered necessary to utilize some form of automatic toll-ticketing device to time and record such calls. Such equipment might be too expensive on a line with 20 parties; consequently, all calls in this system are to be charged on a flat-rate basis. One of the purposes of this installation is to study the advisability of this method. All toll calls will go through a regular toll operator.

Operation

In a mobile telephone system with a dial at both ends, signalling can be done generally in one of two ways: First, the dial can make or break a tone which modulates a radio carrier or, second, the dialed digit can be stored and translated into one or more steady tones, each tone or series of tones different for each digit from 1 to 0. In this system both methods are used. Signalling from the base station to the mobile unit is accomplished by sending out two tones (between 300 and 500 cycles) to operate a pair of resonant reed relays at the mobile end. This method is the most economical for the small number of mobile stations involved because the telephone equipment effectively translates the dialed number directly into an operation of one of ten sensing relays in the control equipment.

Signalling in the reverse direction (mobile to base station) is accomplished by transmitting a gate frequency (2,000 cycles) when the dial is taken off normal, and a pulse frequency (1,500 cycles) when the dial is released. These tones are received at the base station and are converted directly into d-c pulses to select the called land subscriber. This eliminates a larger number of oscillators at the mobile station, together with storage and translation equipment to change the digit dialed into multiple tones A simplified diagram of both signalling circuits is shown in Figs. 1 and 2.

In a call initialed by a land subscriber his radio transmitter is operated when the mobile radio number is dialed (usually on the second to the last digit dialed). Reception of this signal at all mobile units on this channel will operate their busy lamps. This indicates to the mobile subscriber that the channel is in use, but does not prevent him from breaking into an existing conversation if an

Paper 57-1020, recommended by the AIEE Communications Switching Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 7-11, 1957. Manuscript submitted July 26, 1957; made available for printing March 21, 1958.

R. P. Dimmer is with the General Telephone Laboratories, Inc., Northlake, Ill.

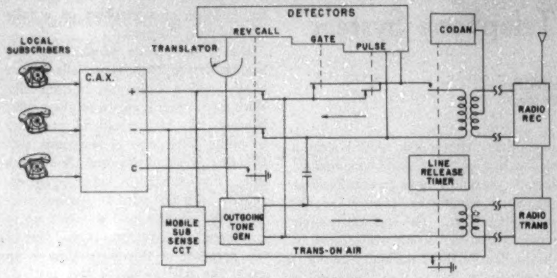

Fig. 1. Block diagram of land station

emergency exists. If he should break into an existing call, he cannot release the circuit on hang-up.

The called ringing voltage, usually obtained on the last digit dialed, will operate one of the ten sensing relays in the control circuit. These relays are a resonant vibrating type of device which will respond to any one of the ringing frequencies between $16\frac{2}{3}$ and 66 cycles per second. They will select two oscillator frequencies corresponding to the number of the subscriber being called, and place them on the radio carrier. These tones will follow the ringing period.

In the mobile unit of the called subscriber, reception of these tones will operate two resonant relays which in turn will operate the buzzer. Operations of these various relays and buzzer will follow the ringing period of the telephone system.

When the mobile subscriber answers, removal of his handset from the dash unit automatically places his radio transmitter on the air for 2 seconds. This brief signal at the base station receiver causes tripping of the ringing cutoff relay in the telephone equipment, and removes the ringing voltage and tones from the circuit. The circuit is now complete, and conversation can ensue.

If the wire line telephone should disconnect first, the connector would release and start to put the called mobile telephone on line lockout. The auxiliary cutoff relay at the radio equipment would then release along with the regular central office cutoff relay. This would open the central office loop and turn off the fixed transmitter without waiting for the disconnect from the mobile subscriber to release the central office loop and radio channel. Should the mobile subscriber then disconnect after the connection had been released by the wire line telephone the fixed radio transmitter would have been turned off and the radio loop already opened, so that the mobile disconnect would not do anything at the fixed radio station.

In a mobile-initiated call removal of the handset from the dash unit again automatically places its radio transmitter, plus tone, on the air for a moment. Reception of this signal turns on the wire-line radio transmitter, and seizes an idle incoming selector in the telephone equipment. Dial tone is returned via this transmitter to the mobile receiver. The mobile subscriber may then dial in the usual way. All tones (busy tone, ring-back tone, etc.) normally associated with automatic telephone equipment can be heard by the mobile subscriber.

When the dial in the mobile unit is taken off normal it turns on the mobile radio transmitter and sends out a tone to operate the gate relay in the land station. This relay remains operated until the end of the pulsed digit because of its slow-release characteristic. Operation of the gate relay removes a shunt on the contacts of the pulse relay and permits it to function. When the dial is released, the pulse relay follows, and breaks the d-c loop circuit into the telephone equipment at a pulse rate. At the end of the pulsed digit the gate relay falls back to normal. In this technique, it is necessary that both a long gate and short pulse signals be received before an actual selection can occur at the telephone exchange. In a stand-by condition it would be necessary to operate the gate detector with a long period of noise of the proper frequency at the same time that the pulse detector operates to cause false operation of the telephone equipment.

In a reverting call (mobile to mobile) the incoming pulses from one mobile station are translated in the control circuit into two tones for selecting the other mobile subscriber.

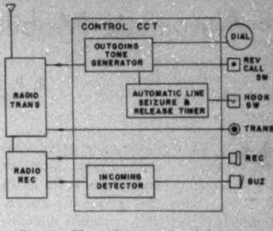

Fig. 2. Block diagram of mobile station

During the time that the mobile subscriber initiates the call to the answer by the wire line subscriber, the telephone line seizure is locked in for a 2.5-minute period. When the wire line subscriber answers, this timer is disconnected from the circuit, together with the gate and the reverting call detectors, to avoid operation on voice. This is accomplished by the use of a reverse battery relay on answer.

When the mobile subscriber hangs up, his radio transmitter is again placed on the air automatically, for 2 seconds with a long 1,500-cycle tone. Receipt of this disconnect signal opens the loop to the central office. If the mobile subscriber had been the first to disconnect, the receipt of this on-hook signal would be displayed back at the connector, so that the connection would be returned to normal when the calling party disconnects. If another mobile station

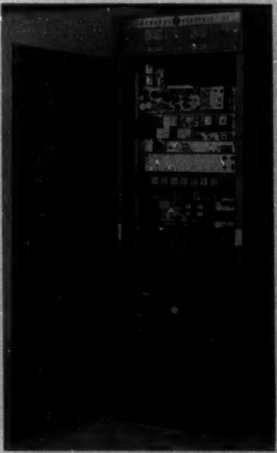

Fig. 3. Fixed or land station

Vol.
Pt. 1
195

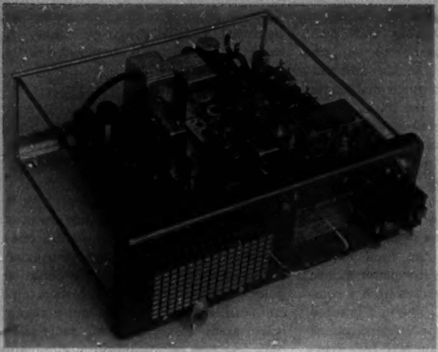

Fig. 4 (left). Mobile station

Fig. 6 (right). Fixed-mobile station desk unit

should attempt to call in the meantime the call would merely land on the already established connection and hence, the station would receive no dial tone. This corresponds to what happens on wire lines; it is necessary to hang up and wait for the called line to be freed by the original calling party.

To guard against failure to receive a disconnect signal from the calling party (the calling party does not restore the handset properly, or the line is in trouble) which would result in tying up the radio channel with the radio transmitter turned on, it is necessary that the telephone switching connectors serving the radio channel be equipped with connector time-out. The time-out equipment at the radio station is of no help on incoming calls to the mobile stations because the central office connector blocks off the calling party's supervisory signals, preventing them from being received at the radio station which is now on the called party's end of the connection.

With automatic time-out provided in the connector group serving the radio channel, any trouble condition resulting in failure to receive a disconnect signal from the operators office or interoffice trunk will be timed out, provided, of course, that the radio channel shows on-hook. In other words, trouble conditions on wire lines or on trunks cannot tie up the radio channel for more than the connector time-out period.

Fig. 5. Mobile station dash unit

If the mobile subscriber wishes to make a reverting call he would press the reverting call button on his dash unit for a moment. This places the mobile transmitter on the air with 2,500-cycle tone. At the base station, reception of this signal would BUSY out the radio circuit to any other land subscriber. This operation would also ready the reverting call translator. The mobile subscriber would now dial two digits: either 01 to 00, or 11 to 10. If he dials 10, for example, the first digit would select the ringing code, and the second digit would select the two ringing tones. When the second mobile subscriber answers, the tone generators and detectors would be removed from the circuit. Again the calling party has power to release the circuit. In this type of call one of the two mobile units must transmit for a moment every 2.5 minutes to prevent the systems' releasing on the timer.

Since automatic time-out is provided at the land radio station for outgoing calls, it is necessary for the mobile station to hang up after dialing an operator for a toll call, and be called back to eliminate this automatic time-out feature which would otherwise open the connection prematurely. This is because the operator trunks cannot reverse the calling party's battery supply; hence, if the mobile station attempted to hold the original connection, it would be automatically timed out and disconnected. The operator would advise the mobile station to hang up and then wait for the disconnect signal before attempting to dial back the station. If this particular disconnect signal should be lost, the operator would merely continue to hold the circuit until the radio time-out provided the disconnect signal automatically. It is also possible to eliminate this call-back requirement by having the mobile subscriber press his talk-to-listen switch momentarily every 2.5 minutes. This causes the automatic timer to reset to zero and start a new timing cycle. On calls of this type the gate and reverting call detectors are removed from operation after a 30-second delay to prevent their operation on speech.

In accordance with Federal Communications Commission requirements the call letters of the base station are transmitted at the end of every transmission. These are transmitted in continental code at a speed of 25 words per minute. One of the outgoing signalling oscillators (500 cycles per second) is used as the tone source.

Equipment

A typical base station is shown in Fig. 3. The unit comprises a 50-watt frequency-modulation transmitter, operating in the 152-megacycle band. These units occupy the upper part of the cabinet. The cabinet houses the control equipment in the lower section. On this panel are located the outgoing tone generators, the three incoming tone detectors, and the necessary relays, switches, and sensing devices to connect to the telephone equipment. A separate power supply, mounted on the bottom, furnishes both high voltage and 48 volts for relay operation, to permit separate operation of the control equipment if desired. For separate operation, four wires connect the control equipment to the telephone exchange, and four wires are required between the control equipment and the radio equipment. The control equipment is designed to be operated from a stronger, all-relay, or cross-bar type of telephone office.

Two types of mobile equipment were used in this trial installation, one 60-watt unit, and one 30-watt unit. Actually, the system will work with any mobile gear. The selector utilizes a 3-inch chassis so as to fit into a standard 17-inch case. It may be externally mounted if so desired. Fig. 4 shows a mobile unit with cover removed.

Fig. 5 shows the mobile dash unit furnished. This unit is of the cradle design, very similar to a conventional telephone except that it has a simple locking device to prevent the handset from bouncing out of the cradle on rough terrain. This unit contains an ON-OFF key-type switch on the side, and ON-OFF, BUSY, and ON-AIR lamps in the upper front. A small reverting call push button switch is mounted on the opposite side visible in Fig. 5. The dash unit contains a hinged bracket which enables the unit to be mounted on the top, front, or bottom of the dash panel of the car. A short cable extends from the dash unit to a small buzzer box usually mounted under this dash panel. This unit contains the volume control, squelch control, buzzer, and the necessary terminals to connect the radio equipment to the dash unit.

The equipment in the fixed mobile station is similar to the low-power mobile unit except that it operates from a commercial power source. The unit is rated in the 15-to-25 watt class. A desk phone is used in this application with the necessary indicating lamps as shown in Fig. 6. In place of a buzzer this unit uses a conventional 60-cycle gong-type ringer. A reverting call button is contained directly under the handset.

Conclusions

Since the development work on this project was started, a large amount of interest has been shown and many new uses considered for this type of a telephone system. There seem to be many places where it might be used to great advantage either as a way of offering quick temporary telephone service, or in places where telephone service does not warrent the expense of poles and wire. Where microwave circuits can eliminate outside plant between urban areas, so an automatic radio telephone system of this type can eliminate outside plant within the urban area.

Magnetic Field Strength in Oersteds Near Large Rectangular Conductors

J. H. MILLER
FELLOW AIEE

A HIGH VALUE of direct current in a conductor produces a high magnetic field which may affect electromagnetic instruments and control gear in the vicinity. The value of the magnetic field in oersteds at a distance d in feet, from the center of a large round conductor, solid or tubular, carrying a current of I amperes is given very simply by the equation,

$$H=0.00656\, I/d \tag{1}$$

A brief tabulation of some representative values is given in Table I.

In the electrochemical industries, including the manufacture of aluminum metal from alumina, the conductor is usually rectangular in shape, consisting of a group of rectangular bus bars. Since the conformation is not circular the preceding equation for field strength cannot be used directly.

To obtain a working procedure to determine the field strength adjacent to a rectangular conductor carrying a high current, it was decided that the laminated bus could be considered as a solid conductor within its outside outline dimensions and that for the purpose of this analysis the point at which the field was to be determined would be on an axis of the conductor cross section.

Referring to Fig. 1, dimensions a and b were assigned as shown, with d the distance from conductor center to the point P, at which the field was to be determined. To allow for a dimensionless formula, parameters were assigned where $A=a/b$, a sort of aspect ratio, and $D=d/b$. In collaboration with W. N. Goodwin, Jr., formerly Chief Engineer for the Weston Electrical Instrument Corporation, a complete integration over the entire rectangular current path for the field at point P gave the following:

$$H'=H\left[\frac{D}{A}\left\{(2D+A)\tan^{-1}\frac{1}{2D+A}-(2D-A)\tan^{-1}\frac{1}{2D-A}+\frac{1}{2}\log\frac{1+(2D+A)^2}{1+(2D-A)^2}\right\}\right] \tag{2}$$

In the foregoing, H is the field at point P if the conductor were circular in section and is obtained from equation 1. The remainder of the equation then may be considered as a modifying factor F, so that we might say $H'=HF$. In the long equation the angles corresponding to inverse tangents are in radians and natural logarithms are used.

Values of F have been calculated for rectangular conductors of various shapes, having a width at right angles to the axis to the point P in question from 20 times the thickness to a width 1/20th of the thickness, and these are plotted in the above chart, using however, the ratio $A=a/b$ to identify the several curves, and

Table I. Representative Values of Magnetic Field H, in Oersteds

	d, Feet					
I, Amperes	1	2	5	10	20	50

Paper 58-367, recommended by the AIEE Indicating and Integrating Instruments Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 6, 1958; made available for printing April 1, 1958.

J. H. MILLER is with Weston Instruments, Division of Daystrom, Inc., Newark, N. J.

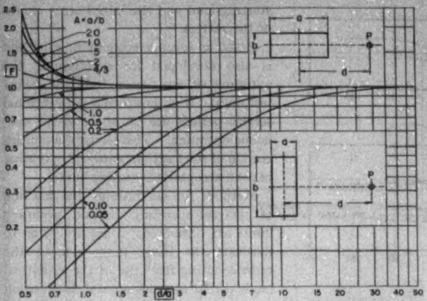

Fig. 1. Plot of values of modifying factor F, used in obtaining magnetic field strength in oersteds near a large rectangular conductor carrying a heavy current

d/a as the ordinates to simplify the presentation.

Essentially, then, to determine the flux density at point P, determine a/b and select the appropriate curve or interpolate between two curves. Determine d/a and select the appropriate vertical ordinate. The intersection of the ordinate and curve gives the value of F on the scale at the left. The value of the field in oersteds, is, then,

$$H' = 0.00656\, I/d(F) \qquad (3)$$

Note that a field of 5 oersteds is ordinarily the maximum field strength for which shielded instruments are rated. In higher fields additional shielding is required. Alternatively, self-shield structures such as the Weston core-magnet mechanism may be adequately shielded for upwards of one-hundred to several hundred oersteds depending on the particular mechanism and casing used.

◆

Discussion

Max Kramer (Aluminum Company of America, Cleveland, Ohio): The resistance paper analog method commonly used to determine magnetic flow lines set up by large rectangular bus structures will give errors caused by variations in the resistance constant of the paper, and errors inherent in the method, for flow lines close to the bus. It is possible by a certain procedure, to translate the flow lines into field strength, and the accuracy of this method is contingent on the trueness of the flow pattern.

The method of calculating magnetic field strength given in Mr. Miller's paper is sufficiently accurate and rapid to encourage common useage. The writer has checked this method against the point-source of current formula, $2I/R$, to determine field strengths of a bus having an outline dimension ratio of 4 to 1. The simple formula can be used with small error for points in space at a distance of at least ten times the bus smaller dimension, the error near the bus outline larger dimension being much less.

To avoid uncertainty in the calculated field strength for points in space, the method offered by Mr. Miller is now used exclusively by the writer. It is possible to calculate the field strengths for points on the two axes of a bus and to draw in the flux flow lines more accurately than can be done with the resistance analog. These flow lines can then be reproduced on the analog paper by ordinary methods of manipulation, and then ferrous structures can be "injected" into the setup to determine flow distortion and to re-evaluate the field strengths.

Some work along these lines has been done.

Evaluation of Single-Phase Metering Practices Based on Meter Performance and Load Characteristics

J. M. VANDERLECK
MEMBER AIEE

Synopsis: To evaluate such choices as rating, type, make, and service period for meters, a method is developed for determining the error in measurement of total energy taken by customers. Also, a method is developed for determining the optimum economical service period for meters. In a discussion of statistical methods for estimating the fraction of meters operating beyond acceptable accuracy limits, it is shown that normal distribution of meter errors should not be assumed. Findings are presented regarding meter errors, customers' load characteristics, error in total energy measurement, optimum service period, and fraction of meters operating beyond accuracy limits. It is concluded that the present ruling on length of service period should be changed to one that limits the fraction of meters beyond accuracy limits. This ruling should lead to improved metering and very significant savings because of longer service periods.

IN METERING the loads of single-phase customers, a large proportion of the cost is caused by the necessity for periodically servicing the watt-hour meters. The total cost of servicing a meter may well exceed the purchase price of the meter, even if the meter is serviced only three times during its life. The maximum length of the period between servicing operations (service period) is usually determined by a regulatory authority. Canadian Government regulations permit modern meters to operate 8 years before reverification of accuracy. No doubt the limit selected is based on judgment regarding the long-term accuracy of meters. It would be to the ultimate advantage of the utilities if the long-term accuracy were improved, because longer service periods would likely be permitted and, in addition, less revenue might be lost from the increase of minus errors as the length of service increases. It is estimated that roughly 3 million dollars a year is spent in Canada to service meters periodically, and roughly ten times this amount in the United States. This is based on an estimated average service period of 8 years, and an estimated average cost of 6 dollars per servicing operation. By reducing the need to service meters to one replacement by a new meter every 32 years, the servicing costs

Y., June 22–27, 1958. Manuscript submitted March 1, 1958; made available for printing April 30, 1958.

J. M. Vanderleck is with The Hydro-Electric Power Commission of Ontario, Toronto, Ont., Canada.

The author acknowledges the valuable contributions on statistical methods and analysis by J. G. C. Templeton of The Hydro-Electric Power Commission of Ontario.

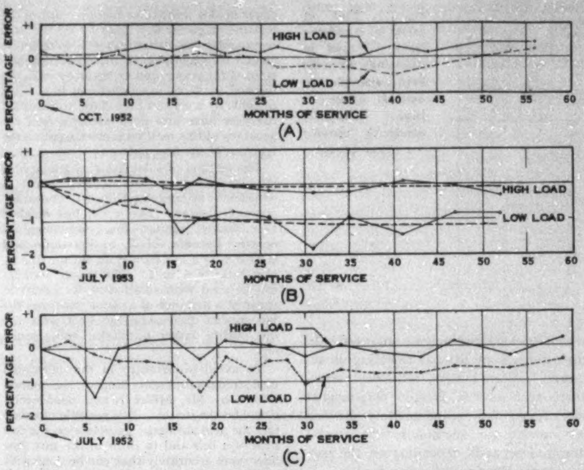

Fig. 1. Mean error of samples of meters operating outdoors. Five makes of meter in each sample with high load of 2,900 watts, low load of 460 watts, and 230-volt 3-wire 60-cycle 1-phase rating

A—Sample A: rating, 15 amperes nominal; 29 meters; continuous load, 2,900 watts; initially adjusted to zero error indoors

B—Sample B: rating, 25 amperes nominal; 15 meters; continuous load, 2,900 watts; initially adjusted to zero error indoors

C—Sample C: rating, 15 amperes nominal; 25 meters; continuous load, 460 watts; initially adjusted to zero error outdoors

become roughly one quarter (8/32) of the present-day costs, thereby saving millions of dollars.

The importance of knowing the error in measurement of the total energy taken by domestic and rural customers is reflected in the following figures. In 1955, the total revenue from such customers was about 200 million dollars in Canada[1] and about 3 billion dollars in the United States.[2] A loss of revenue of only 0.1% due to meter errors amounts to a loss of 3.2 million dollars per year to the electrical utilities in the two countries.

Information on the accuracy of meters is usually obtained from tests made at the end of a service period of several years. Such data are very useful to indicate the percentage of meters that have errors within specified limits at specified test points. However, from such data alone, one cannot determine the accuracy with which the total energy taken by customers has been measured. Consequently, the influence of meter errors on revenue is not known. For this reason, the author's utility has obtained additional test data on both meter performance and customers' energy-consumption (load) characteristics. The test results obtained from pilot samples of meters and customers are given in this paper. A method is developed for determining from the test results, the error in measurement of total energy. The method provides logical weighting of the meter errors found at the low-load and high-load test points, and adds the bias resulting from the minimum starting load and the initial error curves of the meters.

Based on revenue economics, a method is also developed for determining the optimum service period from the meter test data. It is shown that conventional service periods are far short of the economic optimum. This leads to a consideration of the fraction of meters operating beyond acceptable accuracy limits.

Methods for determining the fraction of meters operating beyond accuracy limits are compared. Data are given to illustrate the likely magnitude of the error resulting from use of the statistical method that assumes normal distribution of meter errors. The fraction of meters that measure the total consumption beyond limits is compared with the fraction that is found beyond limits from conventional as-found accuracy checks. Finally, consideration is given to the change of the fraction beyond limits relative to the length of service of the meters. Conclusions are reached with respect to the improvement that could result from a change in the regulations regarding the maximum service period.

It is suggested that the selection of meter types, ratings and operating practices should be based on the results of studies similar to those described in the paper.

Total Energy Measurement and Optimum Service Period

TESTS

To estimate the accuracy with which the total consumption would be measured by certain types or ratings of meters, test data were obtained on meters in simulated service for a number of years, and also on customers' load characteristics. The changes of error with duration of

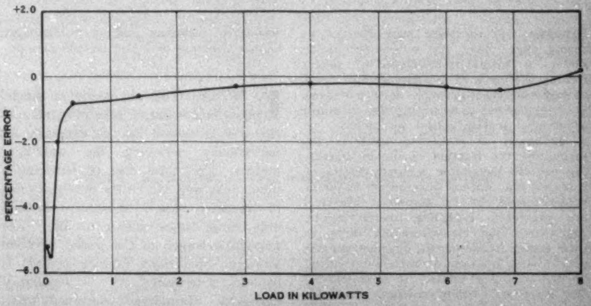

Fig. 2. Average error curve for sample B after 52 months of service; rating, 25 amperes, 230 volts, 3-wire, 60 cycles; 15 meters

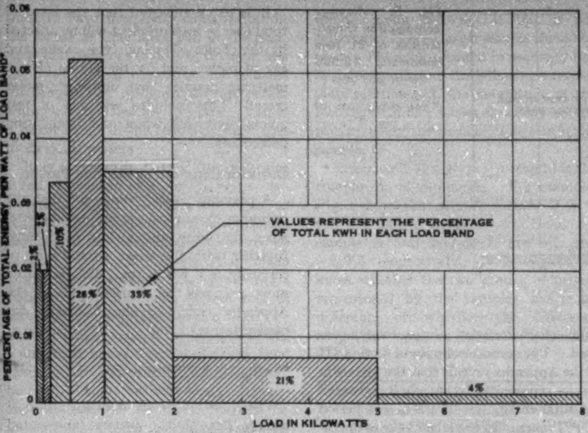

Fig. 3. Average consumption characteristics of 17 farm customers, 4,600 kw-hr per year

* If load band spans a range of 300 watts, then the percentage of total energy within the load band is 300 times the value of the ordinate

outdoor service are shown for three pilot samples of meters in Fig. 1. All meters were adjusted initially to substantially zero error, and then each meter was checked periodically for several years. Tests are continuing. It is apparent that the meters in sample A, Fig. 1(A), have maintained accuracy much better than those in sample B, Fig. 1(B). The errors of sample B meters at the high-load and low-load test points are used in the Appendix to compute the error in measurement of customers' total consumption over a period of several years. Also required to perform the aforementioned calculation are the average meter characteristics of error versus load, henceforth called the average error curve. In Fig. 2 is given the average error curve of sample B meters measured one day during the fifth year of service. Obviously, this curve does not apply at other times when the errors at the low-load and high-load test points are different from the values shown on the curve. The load curve at other times can be determined from a knowledge of the errors at the low-load and high-load test points. This subject is developed later in the paper.

Customers' load characteristics were obtained by conducting a pilot load survey. The object was to find the relative amounts of energy taken by customers in various load bands. This was accomplished by specially metering the load of each customer in the sample. Either an instantaneous recording wattmeter or a load-analyzing unit was installed at the customer's service entrance for an interval of 2 to 4 weeks. The survey extended throughout all seasons. The results are shown as histograms for three different groups of farm customers in Figs. 3 through 5. The groups differ in average annual consumption from 4,600 to 12,500 kw-hr (kilowatt-hour).

The histograms in Figs. 3 and 5 were obtained by integration of load charts. The charts were divided into 5-minute intervals, and the energy in each interval was allocated to the appropriate load band. Fig. 4 was obtained more simply from two load-analyzing meters which are described in the literature.[3] The meter used has four sets of dials that read directly the energy taken in each of four load subranges. The subranges for one meter are 0 to 240 watts, 240 to 600 watts, 600 to 2,400 watts, and all over 2,400 watts. The other meter enabled the 0 to 240-watt subrange to be divided into four, namely, 0 to 10 watts, 10 to 20 watts, 20 to 50 watts, and 50 to 240 watts.

Error of Total Energy Measurement

The errors of a meter at various loads and any point in time can be represented by an error curve. The curve may be expected to change with time in a complex manner. There may be both daily and seasonal fluctuations of each point on the curve, as well as a long-term drift.

In any event, if the mean value of error is determined at each load point during the entire interval of interest and if the percentage of total energy taken by the customer per increment of load is determined at each load point, then by combining the two curves, the error in measurement of the total consumption is obtained.

To obtain mean values of error at each load point during the entire interval it is necessary to measure periodically in service the meter errors at only a low-load test point and a high-load test point, and to measure the error curve of the meter only once. These measurements are sufficient because any change in the percentage error curve of a meter can be reduced approximately to a combination of a constant change independent of load, and a variable change inversely proportional to load. For example, when errors are small, a change in drag-magnet strength causes an equal change in percentage error at every load, and a change

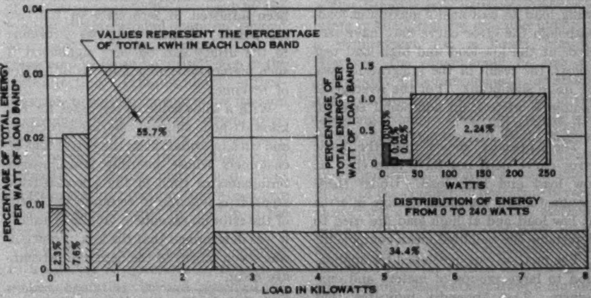

Fig. 4. Average consumption characteristics of 12 farm customers, 7,650 kw-hr per year

* See subcaption of Fig. 3

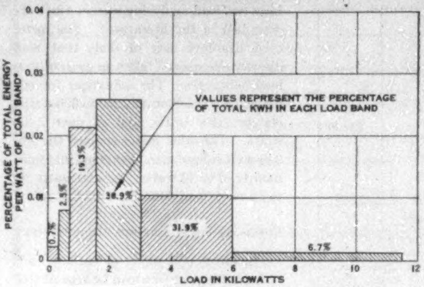

Fig. 5. Average consumption characteristics of 21 farm customers, 12,500 kw-hr per year

* See subcaption of Fig. 3

in friction has an effect inversely proportional to the load.

However, the method developed in section I of the Appendix avoids the calculation of the mean values of error at each load point. Instead, the error in total consumption is shown to be the sum of several components. One component is determined from the weighted mean of the mean values of error measured at low load and high load during the interval of interest. The weighting is based on the customer's load characteristics. A numerical example in section III of the Appendix reveals that the load characteristics given in Fig. 3 result in the following weighting when low load is 460 watts and high load is 2,900 watts:

$$(0.58\times\text{low-load error})+(0.42\times\text{high-load error})$$

Another error component results from the failure of the meter to register any of the energy taken below the minimum operating load. In the numerical example, this amounts to an error of about -0.1%. The remaining error component is the result of integrating the basic error curve of the meter with the customer's load characteristics from minimum operating load to customer's maximum load. Although the error curve may have zero error at the low-load and high-load test points, the result of the integration may be quite significant. For the average of sample B meters, an additional error of -0.2% was found.

The Appendix shows that the basic error curve need not have zero error at low load and high load. Under these circumstances, the mean change in error at low load and at high load are used to determine the weighted mean component.

The method was developed for application to large groups of meters and customers. The Appendix indicates that the method for one meter is applicable if average values of meter and customers' load characteristics, respectively, are used. The second example in section III of the Appendix reveals that the meters in service represented by sample B registered the total energy low by 0.9% in a period of $4^{1}/_{3}$ years. In the latest year of operation, Fig. 1(B) shows that sample B meter errors averaged -1.2% at low load and -0.15% at high load. The weighted mean error according to the aforementioned weighting is -0.8%. The error in measurement of total energy becomes -1.1% because of the other components of error.

When a utility at the end of a period of service depends on as-found tests in the meter shop to judge past performance, misleading results may ensue. For example, when sample B meters were removed from simulated service and shop-tested, the low-load and high-load test points were found to average -0.8% and -0.3% respectively. Neither these values nor the weighted mean values* would likely lead to a judgment that 1.1% of the total energy in the latest year of service had not been registered. Neither would it be expected that 0.9% of the total energy had not been registered in a period of $4^{1}/_{3}$ years, knowing that initially the meters were new and had been adjusted to zero error at the two test points. The resulting loss of revenue to the utility can be very significant if such meters determine millions of dollars of revenue.

With a knowledge of the rates for the kilowatt-hour steps in the rate structure, and with information on the percentage of customers whose monthly consumption terminates in each of the kilowatt-hour steps, it is possible to estimate the effect of the error on revenue. In one instance, it was determined that the loss of revenue was seven tenths of the negative percentage error.

It is to be expected that the error of total energy measurement will be affected by the choice of rating, type, make, and age of meter, and by the choice of any metering practice that influences meter errors. This includes selection of test points, and calibration and installation procedures.

Optimum Economical Service Period

A previous paper[3] points out that the optimum economical service period occurs when the mean annual loss of revenue together with the mean annual cost of servicing is a minimum. This is stated more precisely by equation 11 in the Appendix (refer to the Appendix for nomenclature):

$$kE_m+\frac{C}{t_1}=\text{a minimum} \qquad (11)$$

The question arises whether group B meters, i.e., all the meters represented by sample B, should be withdrawn from service, reconditioned, and reinstalled. A method based on equation 11 enables this question to be answered. However, the method presumes that after reconditioning, the meters will be returned to service and will repeat the original performance. The economics of replacing the meters by superior ones is not new, and therefore is not included in this paper. The performance of sample A and sample C meters as shown in Fig. 1 indicates that a different rating can reduce the loss of revenue substantially.

Equation 12 in the Appendix reveals that the optimum economical service period occurs at the time when the rate of loss of revenue less the mean annual loss of revenue up to this time reaches the mean annual cost of servicing up to this time. Whether the optimum service period has been reached can be checked with a knowledge of the errors at the low-load and high-load test points during the entire period of service. It is not necessary to know the average error curve (error versus load) of any meter or the whole group at any time. The method is developed in section II of the Appendix, and a numerical example is given for group B meters for $4^{1}/_{3}$ years of service in section IV. The example shows that with:

1. an assumed average annual revenue per customer of $80,
2. the percentage loss of revenue equal to seven tenths of the minus percentage error of total energy measurement, and
3. the cost of servicing equal to $6 per operation per meter,

then the optimum service period has not been reached. In fact, if the meters con-

---

* The Code for Electricity Meters[4] indicates two methods: 1. equal weighting, and 2. high-load error four times the weight of low-load error $(0.2\times\text{low-load error}+0.8\times\text{high-load error})$.

Vol.
Pt. 1

tinue to have increasing minus errors in the future as they have had in the past, such that the rate of loss of revenue less the mean annual loss of revenue remains unchanged, the optimum service period will not be reached for 48 years. This is a direct result of the relatively high cost of servicing meters.

It is noteworthy that if the in-service trend of a group of meters is first to accumulate negative errors, and then to stabilize at a constant error, an optimum economical service period may never be reached. This is because the mean annual loss of revenue kE_m approaches a constant, and the mean annual cost of servicing C/t_1 continues to diminish.

On the other hand, if the trend is toward a uniformly increasing negative error from the start, the optimum service period may be reached comparatively soon. A hypothetical example in the Appendix indicates an optimum period of 14.6 years, if the negative error in measurement of total energy increases 0.1% per year. It may be noted that these hypothetical meters have measured the total energy in 14.6 years with less error than group B meters have in $4^1/_3$ years.

It appears from the curves in Fig. 1 that the optimum economical service period of groups A and C meters will be longer than that of group B meters. Because such periods are greater than the normal lives of meters, it may be assumed tentatively that every endeavor should be made to lengthen the existing period to equal the life of the meter. This leads one to consider other limitations on the length of the service period, such as the fraction of meters operating beyond acceptable limits of error. This subject follows the next section which discusses the significance of results from small samples.

SIGNIFICANCE OF MEAN VALUES

Before drawing conclusions from the test results of samples as small as the pilot samples A, B, and C, the significance of the results should be determined. This can be accomplished readily by assuming that meter errors are distributed normally, and by using published probability methods.[5] For example, during the second and third years of operation of the 29 meters in sample A, the standard deviation of the errors was 1.1% assuming the variance of the group represented by the sample did not change during the interval. Based on these data, the 95% confidence limits for the mean of 29 observations are ±0.4%. That is, there is a 95% chance of being right when it is stated that the mean error for the group is equal to the sample mean ±0.4%. If this is not sufficiently close, a larger sample should be used. The improvement in accuracy can be determined from the following approximate relationship: the magnitude of the confidence limits varies inversely as the square root of the number of meters in the sample.

Reference 5 also gives a method for the comparison of two means. For example, Fig. 1 shows that after 50 months of service, the mean errors at low load for sample A and sample B are 0% and −0.9% respectively. It is desired to know whether the two groups of meters represented by the samples are really different, or whether the difference in the two samples occurred by chance. The method requires these data:

Sample	No. of Meters in Sample	Sample Mean	Standard Deviation
A	29	0	1.5
B	15	−0.9	1.9

The result of the computation indicates that group A meters are really different from group B meters with a 10% level of significance. That is, there is a 90% chance of being correct in the estimate that the mean error of group A meters is different from that of group B meters. Larger samples are required if more certainty about the difference is desired.

Although the sizes of samples A and B are small, it is believed that the inferences drawn from the test results are correct.

Fraction of Meters Beyond Error Limits

In at least one utility where selective sample testing has been adopted, the length of the service period for any group of meters appears to be governed by the fraction of meters found operating beyond acceptable accuracy limits.[7] This is considered to be an important step in the right direction. If the regulatory authorities were to specify the maximum fraction of meters allowed to operate beyond specified limits as the criterion for the maximum service period, then utilities could endeavor to choose meters and adopt meter operating practices that would give a service period equal to the life of the meter.

It would be desirable to have answers to a number of questions in respect to meters operating beyond specified accuracy limits. For example, what is an acceptable method for determining the fraction? Is it correct to assume Gaussian (normal) distribution of meter errors and thus take advantage of the method that employs the standard deviation? How large is the fraction for existing meters at the end of present service periods? How does this compare with the fraction that measures the total energy of customers beyond the limits? Does the fraction of meters that are too fast increase with the length of service? An attempt to answer some of these questions is made in the following paragraphs.

SAMPLE SIZE AND CONFIDENCE LIMITS

Several statistical methods are available for estimating from a sample of meters the fraction operating beyond specified accuracy limits. A discussion of two methods follows. The direct method gives an estimate equal to the fraction observed beyond limits in the sample. Another common method gives an estimate based on: 1. an assumption of normal distribution of the meter errors in the population that is represented by the sample, and 2. the values of the means and standard deviation of the observations of the sample.[7] The reliability of the results depends on the sample size in both methods, and on the accuracy of the assumption in the second method. The reliability of the results can be expressed in terms of confidence limits, as in the following example.

Suppose in a sample of 300 meters, drawn at random from a large population, 3% are observed directly to operate faster than a given accuracy limit. For this sample size, the 95% confidence limits are $1^1/_2$% and $5^1/_2$%.[8] This means there is a 95% chance of being correct in the statement that the fraction of meters in the large population operating faster than the accuracy limit is between $1^1/_2$% and $5^1/_2$%.

The broad range between confidence limits in the foregoing example indicates a requirement for a larger sample. However, the range could be reduced appreciably if the sample mean and standard deviation were used. Suppose in the foregoing example where the sample size is 300, that the method that assumes normality and employs the sample mean, and standard deviation gives an estimate of 3% of the population operating beyond the accuracy limit. Probability methods indicate that the 95% confidence limits are 2% and $4^1/_2$%. Unfortunately, the results of tests for normal distribution of the as-found observations from a number of groups of meters reveal that the observations were not distributed normally. Altogether the as-found checks made at

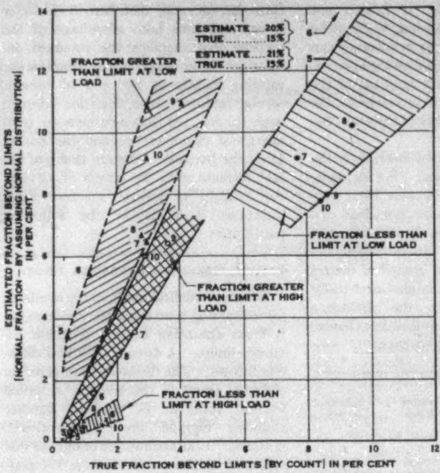

Fig. 6. Relationship between estimated and true fractions of meters beyond limits. Numerals beside plotted points identify the group of meters by years of service; no group contains less than 1,150 meters

low load and high load on five groups of meters were tested. The groups are identified in Fig. 6 by years of service of the meters, which ranged from 6 to 10 years. The number of meters in each group ranged from 1,309 to 6,214. The effects of the abnormal distributions are presented in the following.

ABNORMAL DISTRIBUTION OF METER ERRORS

An illustration of the typical errors that may result from assuming normal distribution is given in Fig. 6. For the five groups of meters mentioned in the foregoing, and one additional group of 1,150 meters, is shown the relationship between the estimated and true fractions of meters operating beyond limits of ±3% error. The estimated fraction was calculated from the mean error and standard deviation of the particular group, assuming normal distribution. The true fraction was determined by actual count of those meters beyond limits. Fig. 6 suggests that when the value of the fraction beyond limits is required, it should be assumed generally that the distribution is not normal unless proved otherwise. For brevity, the estimated fraction assuming normal distribution is termed the "normal" fraction. Note that the true fractions of meters below the −3% limit at low load, and the true fractions above the +3% limit at high load agree somewhat with the corresponding normal fractions. However, the true fractions above the limit at low load are substantially less than the normal fractions, and the true fractions below the limit at high load are substantially more than the normal fractions.

The observations on the group of 1,150 comprise as-found shop checks made on one rating of meter after 4 to 5 years of service. The meters were drawn from one municipality, in contrast to the other five groups which were drawn from various sources. In every instance, observations of meters that did not operate at either low load or high load were not processed.

These findings differ from those reported in a previous publication wherein a normal distribution was indicated for meters that had not been in service.[9] Evidently a reasonable interval of service destroys the normal distribution, at least with respect to the tails of the distribution curve.

Because normal distribution cannot be assumed, a larger sample size is required to obtain satisfactory results. When 95% confidence limits are desired for an estimate based on the fraction of observations found beyond an accuracy limit by direct counting in a sample, values can be obtained by reference to a published chart.[8] The chart gives confidence limits for sample sizes from 8 to 1,000, and for any fraction in the sample beyond a limit. The chart indicates that for 3% of a sample of 1,000 beyond an accuracy limit, the 95% confidence limits are 2% and 4%. Such results indicate that a sample of 1,000 meters will likely be acceptable.

ERROR IN METERING A YEAR'S CONSUMPTION

The accuracy of a meter is usually judged by the amount of its error at two or three selected test points. Because the function of the meter is to measure the total energy taken by a customer with reasonable accuracy, the best criterion for judgment is the error in measurement of total energy. A period of one year is suggested as a desirable length of time for observing the error. The difficulty of making such observations has precluded judgment on this basis in the past. However, the method outlined previously is practical and probably of sufficient accuracy. This method was used to determine the error in total energy measurement for each of many meters. From this was found the relation between the fraction of meters operating beyond accuracy limits at specified test points and the fraction that measured a year's consumption beyond the same limits. First, data are given for the group of 1,150 meters for which some results were reported heretofore; second, data are given for the meters in sample A.

Table I. Comparison of Fractions of Meters* Beyond Accuracy Limits for Conventional Checks and for Long Period of Operation

† The mean in column 3 is the algebraic average of all observations made during the period.

‡ The standard deviation in column 4 is the square root of the mean of the variances determined for each set of 29 observations made during the period.

§ Column 5 is the standard deviation of the accumulated register readings during the period.

‖ Columns 6 and 7 pertain to the errors computed when measuring customers' loads.

¶ In column 11 a meter is counted outside the accuracy limit if found outside at either low load or high load.

Sample of 1,150 Meters. The sample of 1,150 meters resulted from excluding eight inoperative meters from a larger sample. None of the eight operated at low load, but five of them operated at high load. The results of as-found conventional shop checks are shown in Table I. By actual count, the fraction of meters found beyond the ±3% accuracy limits was 15.5%, which is comprised of 15% too slow and 0.5% too fast. However, after computing for each meter the error in measuring customers' loads, it was found that the fraction of slow meters was reduced to 6.3%, and the fast meters to 0.3%, resulting in a total of 6.6% operating beyond the ±3% accuracy limits. This is a very significant reduction from the former value, namely 15.5%.

The eight inoperative meters could have been included in the results. However, it is preferred to consider these separately. The three that did not operate at high load would normally accumulate no registration in service and thus be promptly discovered. The other five constitute a liability that would add about 0.5 to every value in columns 2, 3, 6, and 7 of Table I. This change does not affect the general conclusions drawn from Table I. To compute the error when measuring customers' loads, the following formula was used for each meter:

$$E = 0.4\ e_H + 0.6\ e_L - 0.1\% \text{ error}$$

The constants are those in equation 15 rounded-off. (Refer to section III of the Appendix.) It is assumed that customers' load characteristics are those given in Fig. 3, and that the as-found checks at high load and low load, namely e_H and e_L respectively, are the mean errors at these two loads in service. It is also assumed that the component of error that results from integrating the basic error curve of the meter with the customer's load characteristics is negligible. Some error has been introduced by the use of average instead of individual customers' load characteristics. The significance of this error remains to be investigated.

The results in Table I for this sample of meters demonstrate that the fraction found operating too slow from as-found shop checks is much greater than the actual fraction too slow in the measurement of energy taken over a long interval. However, the fraction found operating too fast is not much greater than the actual fraction too fast in the measurement of total energy.

Sample A, 29 Meters. Although the sample size is very small, results for sample A are given because this sample has been checked periodically during a 56-month period of simulated service outdoors. Consequently, the mean error of each meter at low load and high load over four intervals ranging from 10 to 13 months is well known. In addition, it is established that at one time all meters were correctly adjusted at low load and high load. This should yield greater accuracy in the determination of error in measurement of energy taken over a long period.

From the *in situ* checks, the fraction was determined of meters found operating beyond accuracy limits of ±2% error. The result is compared in Table II with the estimated fraction that would have operated beyond the same limits when measuring the energy taken by typical customers during approximately a year. Table II reveals that the fraction measuring a year's energy beyond limits is significantly less than the fraction found by *in situ* checks. A discussion of the contents of Table II follows.

During the course of 56 months, 18 sets of observations were made of the meters in sample A. Because of the small sample size, the sample mean and standard deviation likely varied more than the corresponding population mean and standard deviation. Consequently, for each of the four periods of operation in Table II, a common mean and variance were assumed for the observations. The error in measurement over each period of operation was computed by the method outlined in sections I and III of the Appendix. Column 7 in Table II indicates a lower variance for the error in measurement over a long period (one year) of operation. Consequently, columns 10 and 13 show the estimated fractions beyond limits for the long period to be less than the estimated fractions beyond limits based on conventional *in situ* checks. For example, the lowest section of Table II shows that on the average, it is estimated that $5^{1}/_{2}$% of the population of meters would be found faster than the limit at high load, and 7% faster at low load; i.e., between 7% and $12^{1}/_{2}$% of the meters would be faster than the limit. The estimate of the fraction fast for the long interval of measurements is 3%, which is less than half of the former figure. Although the individual estimates may be incorrect, it is believed that the ratios of the estimates are indicative of the truth. Column 11 shows that the actual average fraction of the sample faster than the limit was 4%. The actual average fraction of the sample for the long period of measurement was only $2\frac{1}{2}\%$, which supports the belief stated in the foregoing.

The observations of the register readings of the meters in sample A lend further support to the indication that appreciably fewer meters measure a year's total energy beyond specified limits than are found beyond limits from conventional *in situ* checks. All sample A meters were operating on the same load, namely 2,900 watts. Table II shows that for each of the four periods of operation except the first, the standard deviation of the accumulated register readings, column 5, is significantly less than the standard deviation of the conventional *in situ* checks at high load column 4.

The evidence from the foregoing two samples leads to the probability that far fewer meters, possibly one half or less, will measure customers' consumptions over a 1-year period beyond accuracy limits than will be found operating beyond limits when checked conventionally *in situ* or in the meter shop at two test points. However, the improvement may be mostly in the fraction of meters that are too slow.

Increase of Fraction With Time

Published data reveal that the fraction of meters that are too slow increases with length of service. However, the fraction too fast shows no definite tendency to increase with length of service. A review of some data follows.

Frequency distributions of meter errors after varying periods of service are given by Golds.[8] For one make of meter, the fraction above $+2\frac{1}{2}\%$ error at either low load or high load was substantially the same after 14 years of service as that after 2 years of service. For another make, comparing the data for 4 and 12 years of service, the fraction too fast at low load was substantially unchanged, but at high load increased from 4% to 6% approximately. For a third make, comparing the data for 2 and 14 years of service, the fraction too fast at low load increased roughly from 2% to 4%, but at high load fell from about 5% to $2\frac{1}{2}\%$.

Similar data published by the Canadian Electrical Association[10] for groups of meters after 6 to 10 years of service reveal no substantial increase in the fast fraction at low load, but possibly an increase in the fast fraction at high load. The sample sizes ranged from 1,830 to 16,000 meters approximately. The fraction faster than $+3\%$ error at low load was roughly 2%. The fraction faster than $+3\%$ error at high load increased from about $1\frac{1}{2}\%$ to $2\frac{1}{2}\%$.

The data in Fig. 6 indicate a trend toward an increase in the fraction too fast as the period of service lengthens. However, most of these data are not independent of the data in the previous reference.[10]

It is possible that none of the changes in the fraction too fast mentioned in the foregoing is statistically significant because of the sampling methods used. Where the same sample has been observed for several years, namely sample A, no trend has yet been indicated with respect to a change in the fraction too fast. This is shown in column 12 of Table II.

Optimum Service Period Based on Fraction Too Fast

It has been suggested that the overcharge for energy due to the fraction of meters that operate faster than the positive limit of error could serve as a basis for determining the optimum economical service period from the customer's viewpoint. However, unless the periodic servicing of meters reduces the overcharge, the basis does not appear sound. The possibility that the fraction too fast does not increase with time suggests that the overcharge does not increase with time. It follows that periodic servicing of meters would not reduce the overcharge under such circumstances.

The observations of the meters in sample A were analyzed to find whether the average error increased of the fraction having positive errors. For each meter was calculated the error in measurement of the energy taken by a customer during each of the four successive periods of operation shown in Table II. Positive errors resulted for about half of the meters. The fraction fast averaged $+0.6\%$ error for the first year of operation, and $+0.8\%$ error for the latest year. The increase does not appear to be significant to date.

Summary on Performance of Meters

The performance has been discussed of types of meters that are no longer being manufactured. All meters are now 5 or more years old. However, in some respects even these meters appear to behave better than is generally realized. Indications are as follows:

1. The fraction of meters that measure the total energy with an error beyond specified limits is less than the fraction found operating beyond the limits as a result of conventional as-found accuracy checks.
2. The fraction of meters that operate faster than the specified limit does not appear to increase significantly with the length of the period of service.
3. The overcharge for energy due to the fraction of meters that operate fast, or faster than the limit, does not appear to increase significantly with the length of service.
4. The optimum service period based on loss of revenue and cost of servicing probably is greater than the normal life of meters.

Under these circumstances, servicing meters every 6, 8, or 10 years may well be an unnecessary expenditure with no benefit to the utility or the customer, who must pay ultimately for the service through the charges made for electric energy.

Conclusions

In order to evaluate single-phase metering practices, a method has been developed for determining the error in measurement of total energy taken by customers. The method gives the weighting to be applied to measured errors at the low-load and high-load test points. To this error is added that resulting from the basic error curve of the meter, including the loss of registration of energy taken at loads below the minimum operating load of the meter. The results depend on the customers' load characteristics.

It has been shown that as-found checks in the meter shop may give misleading results regarding the magnitude of error of total energy measurement.

A method has been developed for determining the optimum service period based on revenue economics. Examples indicate that the optimum period likely exceeds the normal life of a meter, and thus it appears desirable to eliminate periodic servicing entirely. In this event, meters would be replaced only at the end of life, normally about 30 years.

After a few years of service, as-found checks generally do not have a Gaussian (normal) distribution. Consequently, the fraction of meters operating beyond acceptable accuracy limits should be found by statistical methods that are not based on this assumption. For reasonable accuracy, the sample size should be about 1,000 for any selected group of meters.

Error data of meters indicate that the

fraction of meters beyond acceptable accuracy limits is appreciably less when based on total energy measurement than when based on conventional as-found accuracy checks. The fraction of meters that operate faster than the upper limit does not appear to increase significantly with length of service. Neither does the overcharge for energy due to a fast group appear to increase significantly with length of service.

The utilities should welcome a change from the present ruling that specifies the maximum years of service of meters before reverification to a ruling that limits the fraction of meters operating beyond stated accuracy limits. This would encourage the replacement of inadequate meters by better ratings and types, and lead ultimately to the installation of meters for a life of say 30 years. The result should be a saving of millions of dollars to the utilities and their customers.

Appendix

Nomenclature

A = constant component of Δe
a = a constant, see equation 6
B = constant relating the variable component of Δe to P
b = constant increase in error per year
C = average cost of one servicing operation of one meter, dollars
c = a coefficient, see equation 7
E = percentage error in measurement of total energy taken by a customer over a period of one or more years
E_m = percentage error in measurement of total energy taken by a group of customers over a period of one or more years
e = percentage error of watt-hour meter at load P and time t
e' = percentage error of watt-hour meter at load P and time t'
e_H = percentage error of watt-hour meter at load P_H and time t
e_H' = percentage error of watt-hour meter at load P_H and time t'
e_{H_1} = average percentage error of group of watt-hour meters at load P_H and time t_1
$[e_H]_{t_0}^{t_1}$ = mean value of e_H

$$=\frac{1}{t_1-t_0}\int_{t_0}^{t_1} e_H\times dt$$

e_L = percentage error of watthour meter at load P_L and time t
e_L' = percentage error of watt-hour meter at load P_L and time t'
e_{L_1} = average percentage error of group of watt-hour meters at load P_L and time t_1
$[e_L]_{t_0}^{t_1}$ = mean value of e_L

$$=\frac{1}{t_1-t_0}\int_{t_0}^{t_1} e_L\times dt$$

Δe = change in percentage error e from reference value e'
$[\Delta e]_{t_0}^{t_1}$ = mean value of Δe

$$=\frac{1}{t_1-t_0}\int_{t_0}^{t_1} \Delta e\times dt$$

Δe_H = change in percentage error e_H from reference value e_H'
$[\Delta e_H]_{t_0}^{t_1}$ = mean value of Δe_H

$$=\frac{1}{t_1-t_0}\int_{t_0}^{t_1} \Delta e_H\times dt$$

Δe_L = change in percentage error e_L from reference value e_L'
$[\Delta e_L]_{t_0}^{t_1}$ = mean value of Δe_L

$$=\frac{1}{t_1-t_0}\int_{t_0}^{t_1} \Delta e_L\times dt$$

k = negative constant relating revenue loss to error $= 1/E_m t_1$
l = average loss of revenue during t_1 years due to E_m, dollars per customer
$m\alpha$, $m\beta$, $m\theta$ = mean values of α, β, and θ respectively
n = number of customers in group
P = load, watts
P_H = load at high-load test point, watts
P_i, P_j = boundaries of load subrange, watts
P_L = load at low-load test point, watts
$P_{\max}$ = maximum load taken by customer
$P_{\min}$ = minimum operating load of watt-hour meter
t = time measured from in-service date of meter, years
t_0, t', t_1 = particular values of t
y = per cent of total energy per incremental watt at load P during period t_0 to t_1 years
y_{ij} = mean value of y between ordinates P_i and P_j
y_m = mean value of y between ordinates P and $(P+\Delta P)$
ϵ = average percentage error in measurement of energy being taken by group of customers at time t
ϵ_1 = average percentage error in measurement of energy being taken by group of customers at time t_1
α, β, θ = variables
α_i, β_i, θ_i = particular values of α, β, and θ
$\Delta\beta_i$, $\Delta\theta_i$ = deviations of β_i and θ_i from $m\beta$ and $m\theta$ respectively
$\psi(P)$, $f(P)$, $f'(P)$, $f_H(t)$, $f_L(t)$, $f(t)$ = functions of variables

I. Error in Measuring Total Energy Taken Over Period of Time

The first object is to determine the error in the measurement of total energy taken by a customer over a period of one or more years of service, using the following test data:

1. The error curve of the meter determined at one time t', namely

$$e'=f'(P)$$

2. The curve of error versus time at the low-load test point of the meter during the period t_0 to t_1 years, namely

$$e_L=f_L(t)$$

3. The curve of error versus time at the high-load test point of the meter during the period t_0 to t_1 years, namely

$$e_H=f_H(t)$$

4. The consumption-versus-load characteristics of the customer during the period t_0 to t_1, expressed as

$$y=\psi(P)$$

where y = per cent of total energy per incremental watt.

The foregoing is clarified by an example. If the mean value of y between loads P and $(P+\Delta P)$ is y_m, then $y_m\times\Delta P$ per cent of the total energy is taken between loads P and $(P+\Delta P)$.

The second object is to determine the error E_m in the measurement of total energy taken by a group of customers over a period of t_1-t_0 years of service, using the data in items 1 to 4, for each customer in the group and for each customer's meter.

It is assumed that the only correlation between the meter error e and the customer's energy consumption per incremental watt y is the direct correlation due to load P. In addition, it is assumed that the meters are assigned to customers in a random fashion such that there is no correlation between the shapes of the error curves of meters and the shapes of the energy consumption curves of customers.

The error curve at any time t can be determined readily if the change in error Δe from the datum value, $e'=f'(P)$, is determined. An expression is developed for Δe.

As an approximation based on the theoretical performance of meters, it is assumed that the percentage registration can be changed only by two factors, one of which is independent of the load P, and the other varies inversely proportional to P. Then when the percentage registration is not far from 100, any change in percentage registration Δe approximately is the sum of two components, of which one is constant and the other varies inversely proportional to the load P. However, the assumptions do not apply at loads below the minimum operating load of the meter. Below the minimum operating load, $e=-100$. Thus

$$\Delta e=A+\frac{B}{P} \text{ above the minimum operating load}$$

$$\Delta e_L=A+\frac{B}{P_L}$$

$$\Delta e_H=A+\frac{B}{P_H}$$

Thus

$$A=\frac{P_H\times\Delta e_H-P_L\times\Delta e_L}{P_H-P_L}$$

$$B=\frac{P_H\times P_L}{P_H-P_L}(\Delta e_L-\Delta e_H)$$

$$\Delta e=\frac{P_H\times\Delta e_H-P_L\times\Delta e_L}{P_H-P_L}+\frac{P_HP_L(\Delta e_L-\Delta e_H)}{P(P_H-P_L)} \qquad (1)$$

For any one value of P, the values of Δe, Δe_L, and Δe_H vary with time t. Integrate each varying change in error with respect to time, and divide by the total time, t_1-t_0. Then

$$[\Delta_e]_{t_0}^{t_1}=\frac{P_H[\Delta e_H]_{t_0}^{t_1}-P_L[\Delta e_L]_{t_0}^{t_1}}{P_H-P_L}+\frac{P_HP_L\{[\Delta e_L]_{t_0}^{t_1}-[\Delta e_H]_{t_0}^{t_1}\}}{P(P_H-P_L)}$$

By definition

$$e=\Delta e+e'$$

thus

$$[e]_{t_0}^{t_1}=[\Delta e]_{t_0}^{t_1}+e'$$

$$[e]_{t_0}^{t_1}=\frac{P_H[\Delta e_H]_{t_0}^{t_1}-P_L[\Delta e_L]_{t_0}^{t_1}}{P_H-P_L}+\frac{P_HP_L\{\Delta e_L]_{t_0}^{t_1}-[\Delta e_H]_{t_0}^{t_1}\}}{P(P_H-P_L)}+e' \quad (2)$$

where

$$[\Delta e_H]_{t_0}^{t_1}=[e_H]_{t_0}^{t_1}-e_H' \quad (3)$$

$$[\Delta e_L]_{t_0}^{t_1}=[e_L]_{t_0}^{t_1}-e_L' \quad (4)$$

The total energy taken by the customer equals the area under the curve of customer's load characteristics:

$$\int y\times dP=100\%$$

The percentage error in measurement of the total energy taken for t_1-t_0 years is

$$E=\frac{1}{100}\int y[e]_{t_0}^{t_1}\times dP \quad (5)$$

This is the required solution. However, evaluation of E can be simplified.

Substitute equation 2 in equation 5. Then, above the minimum operating load

$$E=\frac{P_H[\Delta e_H]_{t_0}^{t_1}-P_L[\Delta e_L]_{t_0}^{t_1}}{P_H-P_L}+\frac{P_HP_L\{[\Delta e_L]_{t_0}^{t_1}-[\Delta e_H]_{t_0}^{t_1}\}}{100(P_H-P_L)}\times\int_{P\min}^{P\max}\frac{y}{P}\times dP+\frac{1}{100}\int_{P\min}^{P\max}e'y\times dP$$

Let

$$\frac{1}{100}\int_{P\min}^{P\max}\frac{y}{P}\times dP=a \quad (6)$$

Substitute and rearrange. Then, above the minimum operating load

$$E=\frac{P_H(1-aP_L)}{P_H-P_L}\times[\Delta e_H]_{t_0}^{t_1}+\frac{P_L(aP_H-1)}{P_H-P_L}\times[\Delta e_L]_{t_0}^{t_1}+\frac{1}{100}\int_{P\min}^{P\max}e'y\times dP$$

Below the minimum operating load

$$E=-\int_{P=0}^{P\min}y\times dP$$

Let

$$\frac{P_H(1-aP_L)}{P_H-P_L}=c \quad (7)$$

If the minimum operating load does not change with time, then over the entire load range

$$E=c[\Delta e_H]_{t_0}^{t_1}+(1-c)[\Delta e_L]_{t_0}^{t_1}+\frac{1}{100}\int_{P=0}^{P\max}e'y\times dP \quad (8)$$

To evaluate E numerically, proceed as follows:

1. Using a step-by-step method of integration, evaluate

$$\frac{1}{100}\int_{P=0}^{P\max}e'y\times dP$$

2. If a histogram is given, y is constant for each subrange of load. Then from equation 6

$$a=\frac{1}{100}\left(y_{12}\log\frac{P_2}{P_1}+y_{23}\log\frac{P_3}{P_2}+\ldots\right)=\frac{1}{100}\sum_{P\min}^{P\max}y_{ij}\log\frac{P_j}{P_i}$$

where y_{ij} is the value of y for the load subrange between P_i and P_j.

3. Evaluate c from equation 7.

4. Evaluate $[\Delta e_H]_{t_0}^{t_1}$ and $[\Delta e_L]_{t_0}^{t_1}$ from equations 3 and 4.

5. Evaluate E from equation 8.

To determine the error E_m in the measurement of the total energy taken by a group of customers, find the mean of n values of E, one value for each combination of meter and customer.

$$E_m=\frac{\Sigma E}{n}$$

where n is the number of customers in the group. From equation 8, the error pertaining to the ith customer and meter is

$$E_i=c_i[\Delta e_{H_i}]_{t_0}^{t_1}+(1-c_i)[\Delta e_{L_i}]_{t_0}^{t_1}+\frac{1}{100}\int_{P=0}^{P\max}e_i'y_i\times dP \quad (9)$$

Consider the general expression:

$$\alpha_i=\beta_i\theta_i$$

Let the mean value of

$$\alpha_i=m\alpha=\frac{\Sigma\alpha_i}{n}$$

$$\beta_i=m\beta=\frac{\Sigma\beta_i}{n}$$

$$\theta_i=m\theta=\frac{\Sigma\theta_i}{n}$$

Let $\Delta\beta_i$ and $\Delta\theta_i$ be deviations of β_i and θ_i from their mean values respectively.

$$\alpha_i=(m\beta+\Delta\beta_i)(m\theta+\Delta\theta_i)$$

$$\frac{\Sigma\alpha_i}{n}=m\beta\times m\theta+\frac{\Sigma(\Delta\beta_i\times m\theta)}{n}+\frac{\Sigma(\Delta\theta_i m\beta)}{n}+\frac{\Sigma(\Delta\beta_i\Delta\theta_i)}{n}$$

$$\Sigma\Delta\beta_i=\Sigma\Delta\theta_i=0$$

$$m\alpha=m\beta\times m\theta+\frac{\Sigma(\Delta\beta_i\Delta\theta_i)}{n}$$

If there is no correlation between β_i and θ_i, then

$$\frac{\Sigma(\Delta\beta_i\Delta\theta_i)}{n}=0$$

Thus

$$m\alpha=m\beta\times m\theta$$

To apply this result to equation 9, assume there is no correlation between:

c_i and $[\Delta e_{H_i}]_{t_0}^{t_1}$

c_i and $[\Delta e_{L_i}]_{t_0}^{t_1}$

e_i' and y_i

Then

$$E_m=c[\Delta e_H]_{t_0}^{t_1}+(1-c)[\Delta e_L]_{t_0}^{t_1}+\frac{1}{100}\int_{P=0}^{P\max}e'y\times dP \quad (10)$$

where the definitions of terms e', e_H, e_L, Δe_H, Δe_L, and y are different from those in equation 8, as follows:

e' = mean percentage error of the group of meters at load P and at time t'

e_H = mean percentage error of the group of meters at load P_H and time t

e_L = mean percentage error of the group of meters at load P_L and time t

Δe_H = change in mean percentage error e_H from reference value e_H'

Δe_L = change in mean percentage error e_L from reference value e_L'

y = mean percentage of total energy per incremental watt for the group of customers at load P, during the period t_0 to t_1 years

For the supporting equations 2 through 7, the modified definitions are:

e = average percentage error of the group of meters at load P and time t

Δe = change in the average percentage error e from reference value e'

e_H' = average percentage error of the group of meters at load P_H and time t'

e_L' = average percentage error of the group of meters at load P_L and time t'

II. Optimum Economical Service Period

Assume that the average loss of revenue, l dollars per customer, is proportional to the error E_m and the number of years of service t_1. In this instance, $t_0=0$, i.e.,

$$l=kE_mt_1$$

In a period of t_1 years, the mean annual loss of revenue is

$\frac{l}{t_1}=kE_m$ dollars per customer per year

If the meters are serviced every t_1 years at a cost of C dollars per meter per operation, then

average cost $=\frac{C}{t_1}$ dollars per year

The optimum economical service period in years occurs when

$$kE_m+\frac{C}{t_1}=\text{a minimum} \quad (11)$$

E_m is the mean error over a period of

Table III. Evaluation of $\int_{P=20}^{P=8,000} \frac{y}{P} \times dP$

Subrange P_i to P_j, Watts*	Percentage of Energy in Subrange	Percentage of Energy Per Watt y_{ij}	$y_{ij} \log (P_j/P_i)$
20 to 50	0.06	0.002	0.0018
50 to 100	1.8	0.036	0.0249
100 to 200	2	0.020	0.0138
200 to 500	10	0.0333	0.0305
500 to 1,000	26	0.052	0.0360
1,000 to 2,000	35	0.035	0.0242
2,000 to 5,000	21	0.007	0.0064
5,000 to 8,000	4	0.0013	0.0006

$$\sum_{P=20}^{P=8,000} y_{ij} \log (P_j/P_i) = 0.1382$$

* See footnote in section III of the Appendix.

time. This suggests that at any time t there exists a value of average percentage error in energy measurement ϵ, $\epsilon = f(t)$

and

$$E_m = \frac{1}{t_1}\int_0^{t_1} \epsilon \times dt$$

The optimum economical service period occurs when

$$\frac{k}{t_1}\int_0^{t_1} \epsilon \times dt + \frac{C}{t_1} = \text{a minimum}$$

This occurs when

$$\frac{d\left(\frac{k}{t_1}\int_0^{t_1} \epsilon \times dt + \frac{C}{t_1}\right)}{dt_1} = 0$$

Because

$$\frac{d\left(\int_0^{t_1} \epsilon \times dt\right)}{dt_1} = \epsilon_1$$

then

$$-\frac{k}{t_1} \times E_m + \frac{k}{t_1} \times \epsilon_1 - \frac{C}{t_1^2} = 0$$

$$k(\epsilon_1 - E_m) = \frac{C}{t_1} \tag{12}$$

Equation 12 reveals that the optimum economical service period occurs at the time t_1, when the rate of loss of revenue ($k\epsilon_1$) less the mean loss of revenue up to this time (kE_m) reaches the mean annual cost of servicing up to this time.

By definition, and from equation 10,

$$\epsilon_1 = c(e_{H_1} - e_H') + (1-c)(e_{L_1} - e_L') + \frac{1}{100}\int_{P=0}^{P\max} e'y \times dP \tag{13}$$

Using equations 10, 12, and 13, the optimum economical service period occurs when

$$kc\{(e_{H_1} - e_H') - [\Delta e_H]_0^{t_1}\} + k(1-c) \times \{(e_{L_1} - e_L') - [\Delta e_L]_0^{t_1}\} = \frac{C}{t_1}$$

$$kc\{e_{H_1} - [e_H]_0^{t_1}\} + k(1-c) \times \{e_{L_1} - [e_L]_0^{t_1}\} = \frac{C}{t_1} \tag{14}$$

With daily and seasonal changes in the errors at the high-load and low-load test points, e_{H_1} and e_{L_1} will fluctuate about a trend, and equation 14 will give a series of different values for the optimum service period t_1. It is reasonable under these circumstances to use the trend line of the measured errors to determine values of e_{H_1} and e_{L_1} for application to equation 14.

If it is desired to know whether the optimum service period has been reached at any time, a set of values for all terms may be tried in equation 14. If the resulting value of the left-hand side of the equation is less than that for the right-hand side, then it can be expected that the optimum service period will occur at a greater value of t_1.

III. Examples of Calculation of Error in Total Energy

The first example applies to one meter and one customer. The second example applies to a group of meters and customers.

Example 1. The customer's load characteristics, $y = \Psi(P)$, are those given in Fig. 3. By averaging several accuracy checks during one year, the low-load error $[e_L]_{t_0}^{t_1}$, was found to be +0.4%. Similarly, the high-load error $[e_H]_{t_0}^{t_1}$ was found to be +0.9%.

An initial measurement of the error curve of the meter indicated no error at the high-load and low-load test points. However, the meter did not operate below a load of 20 watts. Low-load tests were made at 460 watts (P_L) and high-load tests were made at 2,900 watts (P_H). Equation 8 is now applied using the steps given previously.

1. Evaluation of:

$$\frac{1}{100}\int_{P=0}^{P\max} e'y \times dP$$

Between $P=0$ and $P=20$ watts, the percentage of total energy taken by customers is −0.12%.* Above 20 watts, assume that the step-by-step integration of the error curve with the histogram in Fig. 3 gives zero error. Thus

$$\frac{1}{100}\int_{P=0}^{P\max} e'y \times dP = -0.12\%$$

2. Evaluation of:

$$a = \frac{1}{100}\int_{P=0}^{P\max} \frac{y}{P} \times dP = \frac{1}{100}\sum_{P=0}^{P\max} y_{ij} \log \frac{P_j}{P_i}$$

From Table III:

$a = 0.00138$

3. From equation 7:

Table IV. Evaluation of $\frac{1}{100}\int_{P=0}^{P=8,000} e'y \times dP$

Subrange P_i to P_j, Watts	Mean Percentage Error Between Ordinates P_i and P_j e'	Percentage of Energy in Subrange	Percentage Loss of Energy in Subrange
0 to 20	−100	0.12	0.12
20 to 50	−5.05	0.06	0.003
50 to 100	−5.35	1.8	0.096
100 to 200	−4.13	2	0.083
200 to 500	−1.4	10	0.14
500 to 1,000	−0.75	26	0.195
1,000 to 2,000	−0.6	35	0.21
2,000 to 5,000	−0.25	21	0.053
5,000 to 8,000	−0.25	4	0.010

$$-\frac{1}{100}\int_{P=0}^{P=8,000} e'y \times dP = 0.91$$

$c = 0.42$

4. In this instance:

$[\Delta e_H]_{t_0}^{t_1} = +0.9\%$

$[\Delta e_L]_{t_0}^{t_1} = +0.4\%$

5. Equation 8 reduces to:

$$E = 0.42[\Delta e_H]_{t_0}^{t_1} + 0.58[\Delta e_L]_{t_0}^{t_1} - 0.12 \tag{15}$$

Substituting the values for $[\Delta e_H]_{t_0}^{t_1}$ and $[\Delta e_L]_{t_0}^{t_1}$ gives:

$E = +0.5\%$

This is the error in measurement of the total energy taken by the customer during the year.

Example 2. The customers' average load characteristics, $y = \Psi(P)$, are those given in Fig. 3. For sample B meters, the average errors of the sample at the low-load and high-load test points were measured *in situ* periodically for 52 months. The mean value at each test point was determined for the entire period, $t_0 = 0$ to $t_1 = 52/12$ years.

At low load, the resulting mean error $[e_L]_{t_0}^{t_1}$ was −0.92%. At high load, the resulting mean error $[e_H]_{t_0}^{t_1}$ was −0.02%. The average error curve determined at one time for sample B is given in Fig. 2. From this curve

$e_L' = -0.80 \qquad P_L = 460$ watts
$e_H' = -0.27 \qquad P_H = 2,900$ watts

Thus

$[\Delta e_L]_{t_0}^{t_1} = -0.12\%$

$[\Delta e_H]_{t_0}^{t_1} = +0.25\%$

As in example 1, $c = 0.42$.

During the 52-month period, assume that the minimum starting load of the meters in the sample was 20 watts. Then the error curve in Fig. 2, $e' = f'(P)$, must be integrated with the customers' consumption characteristics in Fig. 3, $y = \Psi(P)$, between zero and 8,000 watts. This is done step by step in Table IV. The result is

$$\int_{P=0}^{P=8,000} e'y \times dP = -0.91\%$$

This includes the percentage error due to the energy taken between 0 and 20 watts = −0.12%.

---

* In Fig. 3, the first load subrange, 0 to 100 watts (which includes 2% of the total energy), has arbitrarily been divided again into three narrower load bands, 0 to 20, 20 to 50, and 50 to 100 watts respectively. The amounts of energy taken in these respective bands are as 0.04 to 0.02 to 0.6. These ratios are based on the data for very low loads shown in Fig. 5. In this figure, it is assumed that 0.6% of the total energy is taken between 50 and 100 watts.

Equation 10 reduces to

$$E_m = 0.42[\Delta e_H]_{t_0}^{t_1} + 0.58[\Delta e_L]_{t_0}^{t_1} - 0.91$$

Substituting the values for $[\Delta e_H]_{t_0}^{t_1}$ and $[\Delta e_L]_{t_0}^{t_1}$ gives:

$$E_m = -0.87\%$$

This indicates that the total energy taken by customers having meters similar to those in sample B was registered low by approximately 0.9% in a period of 52 months.

IV. Samples of Calculation of Optimum Service Period

Because groups of meters tend to have increasing minus errors as the length of service increases, the first example applies to a uniformly increasing error for the group. The second example applies to sample B meters.

Example 1. With uniformly increasing error:

$$\epsilon = bt$$

From equation 11, the optimum economical service period is t_1, where

$$k\left(bt_1 - \frac{bt_1}{2}\right) = \frac{C}{t_1}$$

$$t_1 = \sqrt{\frac{2C}{kb}} \text{ years} \qquad (16)$$

If the increase in error ϵ/t is −0.1% per year, then $b = -0.1$. If the average annual revenue per customer is $80, and if the percentage loss of revenue per year is seven tenths of the minus percentage error, then $k = -0.56$. If the cost of servicing C is $6.00 per operation per meter, then from equation 16 the optimum service period t_1 is 14.6 years.

Example 2. Equation 14 is applied using the measured data obtained on sample B meters, and using the histogram shown in Fig. 3. A test will be made to find whether the optimum economical service period has been reached after 52 months of service.

Assume that the dashed lines in Fig. 1(B) represent the trend curves to be used to determine values for e_{H_1} and e_{L_1}, at time $t_1 = 52/12$ years. From Fig. 1(B):

$e_{H_1} = -0.17\%$ $\qquad P_H = 2{,}900$ watts

$e_{L_1} = -1.20\%$ $\qquad P_L = 460$ watts

As in example 2 of section III of the Appendix:

$$[e_H]_{t_0}^{t_1} = -0.02\%$$

$$[e_L]_{t_0}^{t_1} = -0.92\%$$

$$c = 0.42$$

Assume that $k = -0.56$ and $C = \$6.00$, as in the foregoing example. Substitute values in equation 14.

left-hand side = $0.126 per customer per year

right-hand side, $C/t_1 = \$1.38$ per meter per year

Because the left-hand side is less than C/t_1, the optimum economical period has not been reached.

From equation 12, the left-hand side of equation 14 equals $k(\epsilon_1 - E_m)$. Suppose the errors of sample B meters continue to increase such that $k(\epsilon_1 - E_m)$ remains constant and equal to 0.126, then the optimum service period will be

$$\frac{C}{k(\epsilon_1 - E_m)} = 48 \text{ years approximately}$$

Discussion

L. B. S. Golds (Eastern Electricity Board, Ipswich, England): Economics of metering is a complicated subject and I agree that it is helpful and indeed necessary to employ statistical techniques to bring the mass of data into a manageable form. One must, however, be careful that such techniques are not pressed to fulfill a function which is beyond their capabilities.

Mr. Vanderleck suggests that the service period of meters should be determined by the percentage of meters registering outside the statutory limits. This is one of the criteria upon which the period might be based, but up to the present it does not appear that a statutory authority would recognize officially that any meter may register energy outside the legal tolerances; although, from a practical and theoretical standpoint, it must of course be recognized that such a possibility exists. The difficulty lies in making statutes to fit statistical theory.

Referring to the assessment of the percentage of meters registering the energy outside the tolerances it is stated in the paper that this percentage may be obtained by a count of the meters in the sample, and when compared with the calculated figure derived from the knowledge of the average error and standard deviation there is an

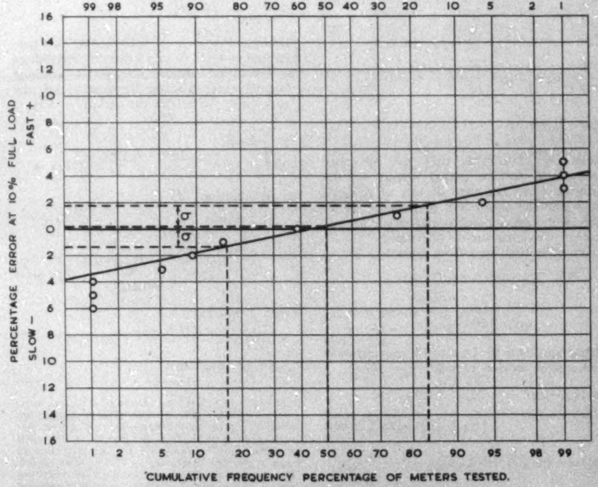

Fig. 7. Cumulative percentages of off-circuit errors

appreciable difference. The author, I believe, suggests that the count is the "true" fraction. Is this "true" figure really true, or is not the true figure obtained only by testing the whole population?

Further, the author arrives at the conclusion that the frequencies of errors of meters tested after return from service are not distributed normally. This conclusion will, of course, apply to a sample drawn from a mixed "population," but I cannot agree with the conclusion when the sample is drawn at random from the same population. In Fig. 7 the cumulative percentages of off-circuit errors of a certain type and make of meter are plotted on probability graph paper. These meters had been in service for approximately 14 years and it may be seen that normality is indicated between 5% and 95% of the meters tested. As would be expected the frequency with which errors occur exceeding 5% and 95% of the total will be so low that very large numbers of meters would be needed to show that the errors were not normally distributed. This subject was dealt with by Josephs in 1943.[1]

I may have misinterpreted the figures in the paper but it appears that the high- and low-load test points are fairly close together on the curve of the meter, i.e., 2,900 watts and 460 watts, and the reason for selecting these points is not clear to me.

The author points out rightly that the error of total energy measurement is affected by the choice of rating, type, make, and age of the meter for a particular service. The proper choice can increase the service life of the meter materially and result in meters being available for a longer period of service leading to a saving of capital expenditure upon new meters.

I am naturally gratified that the investigation which I initiated in the United Kingdom has been pursued by the author and trust that the importance of efficient metering will be generally recognized in the future in other countries.

J. M. Vanderleck: In reply to Mr. Golds, the literature[1] reveals that the regulative authorities in six states of the United States have authorized the use of sampling procedures in place of periodic testing of all meters. Such procedures permit a small percentage of meters to operate with relatively large errors.

With respect to the fraction of meters registering outside specified error tolerances, the paper discusses the true fractions and normal fractions of six groups of meters with 1,150 to 6,214 meters per group. In no instance was the true fraction intended to be taken as that of a population represented by the group as a sample; that is, the groups are considered as entire populations.

Possibly all six groups are mixed populations as Mr. Golds suggests. If so, then a utility's problem is to sort most of the meters into "pure" populations, these having normal distributions by definition. The curve given by Mr. Golds appears inconclusive because of the uncertain distribution of errors at the two tails of the curve. Since the percentage of meters outside of the tolerances are the essential data, the tails are important.

The values of low load and high load chosen, namely 460 and 2,900 watts respectively, were those prescribed by the regulative authority for the ratings of the meters considered in the paper.

Thermal Impedance of Cooling Fins

E. J. DIEBOLD
MEMBER AIEE

WERNER LUFT
NONMEMBER AIEE

Synopsis: Cooling fins of equal thickness and known heat transfer have a definite thermal impedance which is hard to determine analytically. Computing generally valid curves of normalized variables eliminates most of this analysis and establishes simple relations for design parameters and impedance. Optimum design proportions appear in the analysis, eliminating the trial-and-error approach to find them. Comparative analysis of cooling systems is facilitated.

SEMICONDUCTOR DEVICES have widespread acceptance because of their ability to handle large amounts of power although they are extremely small. Having little cooling surface of their own, effective heat dissipation is possible only by conduction to a heat exchanger whenever an appreciable amount of heat is generated. Maximum working temperature of a device is usually determined by the limit of reliable performance, whereas the ambient temperature and the cooling medium depend on the application and may assume rather extreme conditions in military gear.

Devices without the integral heat exchanger usually have a substantial mounting stud, which is advantageous for cooling by bolting to a metal plate which acts as a cooling fin. Under given conditions of heat generation, maximum permissible device temperature, ambient temperature, air pressure, radiant heat from other sources, available air flow, allowable space, and multiple connections, the designer should find an efficient and economic cooling fin, preferably using standard materials. Considering all these limitations, the designer may have to settle for the best possible solution under the circumstances. The present analysis has the objective to facilitate this, using a minimum of numerical work and giving a best possible insight into the potential solutions.

Generally, the subject of cooling fins is well covered in the literature.[1-3] (The bibliographies of references 2 and 3 are of value.) However, because of the many different applications of cooling fins, the available literature is often too broad to be of immediate use for cooling semiconductors. The objective, then, is to narrow down the analysis to specific problems, by using the following restrictions:

1. Results of the mathematical analysis are presented as curves covering a wide range but without extreme accuracy, knowing that many design parameters are too inaccurate to permit a more careful analysis and assuming that designers are unwilling to use lengthy numerical methods to gain a fictive accuracy.

2. Results are normalized, using the base of the device to be cooled as reference dimensions.

3. Geometric restrictions consist of a thin, wide fin with equal thickness, and constant cooling conditions over the whole area.

Within these restrictions the analysis offers basic concepts of general validity permitting direct comparison of widely different versions. Depending upon the design problem (e.g., improvement of existing devices, planning of entirely new equipment, comparison of competing versions) different modes of approach are needed. The analysis therefore shows several different concepts for the solution of the same problem.

Method of Approach

Heat generated in the active part of a device flows through different paths into

---

Paper 58-926, recommended by the AIEE Semiconductor Metallic Rectifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 12, 1958; made available for printing April 23, 1958.

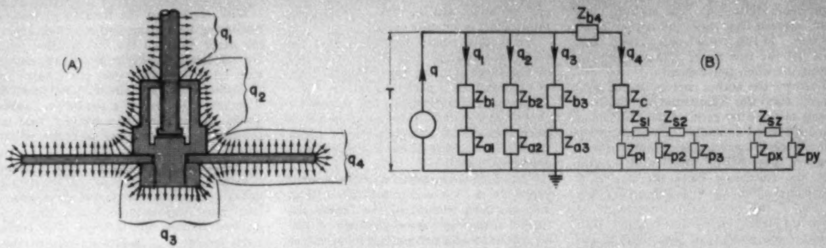

Fig. 1. A—Schematic representation of heat dissipation from a semiconductor device. B—Equivalent electric circuit of (A)

the ambient space. Comparing the flow of heat to an electric current, the temperature rise over ambient to an electric potential above ground and the thermal impedance to the electric resistance, an electric circuit model can be made. Fig. 1(A) shows an example of heat dissipation, and 1(B) the equivalent electric circuit. Heat is generated at the rate q per second; it causes a temperature rise T in the heat generator, and is dissipated along several paths to the ambient.

Heat flows away through the lead at the rate q_1; it encounters the internal thermal impedance Z_{b1}, and the external heat transfer impedance Z_{a1}. Similarly, heat flows as q_2 through the body of the device above the fin and as q_3 through body and hardware below the fins. Corresponding impedances are marked internally as Z_{b2}, Z_{b3}, and externally as Z_{a2}, Z_{a3}. If the device is tested without fin, these series-parallel connected impedances are measured as a lump figure Z_d.

If a cooling fin is attached to the device, a major part of heat flows as q_4 through the internal impedance Z_{b4} and the contact impedance Z_c into the cooling fin. These two impedances may be determined as a lump sum Z_i.

Lumped impedances of the device, as determined in the foregoing, are always approximately the same (except for a temperature correction). It is worth while to determine these impedances accurately as an average from many samples. For the cooling fin, however, the material, the kind of cooling, and the shape, size, and thickness may vary, and unless a good analytical method is available any new cooling fin or alteration on an existing one represents a testing problem. Accordingly, this analytical method concentrates on the cooling fin alone.

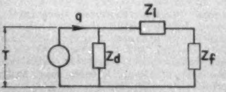

Fig. 2. Simplified equivalent circuit of heat dissipation

Fig. 1(B) illustrates the problem of the distributed series and parallel thermal impedances which is particular to cooling fins. As the heat penetrates into the fin and spreads out, it encounters an infinity of infinitely low (but different) series impedances Z_{s1}, Z_{s2}, etc.; they decrease as the radius increases. Simultaneously, heat escapes from both sides of the fin through the parallel impedances Z_{p1}, Z_{p2}, etc., which are infinitely high but which decrease relatively as the radius increases. These impedances are represented as an interrupted chain in Fig. 1(B). There is no elementary way to find a lump impedance Z_f to replace such an infinite chain of varying elements; the following analysis, however, solves the problem by the use of generally valid data in the form of graphs.

The thermal impedance problem then resolves to a simple model shown in Fig. 2, wherein the heat dissipation impedance Z_d of a device is found by operating it alone in the cooling medium to be used. To find the internal impedance Z_i, the device is fastened to a heat sink of known impedance and the over-all impedance is determined. Knowing also the values of the impedances Z_d and Z_f, Z_i can be calculated. To analyze a new problem the known impedances Z_d and Z_i are combined with a fin impedance Z_f to form a new over-all impedance.

ASSUMPTIONS

Semiconductor devices and their cooling fins operate under various ambient restrictions, which prevent accurate determination of thermal impedances, except in very special cases. Accordingly, the analysis may be made, based on rather summary assumptions, with the knowledge, however, that the results should be applied with caution. The following assumptions give good practical results, particularly in comparative analysis; their validity is discussed in reference 1.

1. Heat transferred from metallic fin to air is proportional to the difference of temperature, and the factor of proportionality is the same over the whole fin surface. Since it is, in effect, neither exactly proportional nor actually constant, an average value must be determined for the different temperatures, temperature differentials, and locations on the fin. In extreme cases (such as of boiling fluids, or cooling at high temperature in vacuum) this theory offers only rough approximations. Heat transfer coefficients (radiation, convection, forced air) are shown in Appendix I and reference 4).
2. The fin is plane, of unvarying thickness, and homogeneous.
3. The fin is of circular symmetry around the heat source.
4. The fin thickness is small compared to its width and the thermal impedance for heat flow across the fin thickness is negligible.
5. Temperature and heat flow are independent of time.
6. No heat is generated in the fin.
7. The ambient temperature is constant.
8. The inner diameter (of the heat source) is much smaller than the outer diameter of the fin.
9. Heat dissipated from the outer edge of the fin is neglected, or considered by widening the fin by half its thickness.
10. In multiple-fin arrangements the fin spacing is greater than two boundary layers of coolant flow (see discussion in reference 2).

Assumptions 2, 4, 8, and 10 are specific to the application of fins for cooling semiconductor devices, and for this reason the theory here may contradict other theories on cooling fins, although it is correct within the assumptions.

Assumption 3 is most restrictive, and rarely met. It is tolerable because deviations from this condition usually occur

at an appreciable distance from the heat source. As shown in Fig. 3(A), the temperature distance variations in the outer region of the fin are small; hence it is rather unimportant whether the fin is circular, square, or rectangular. If the heat source is located on or close to the edge of the fin, it is advisable to determine the thermal impedance of a larger symmetrical fin, which contains the one under consideration, and to multiply it by the ratio of the symmetrical over the unsymmetrical area.

NOMENCLATURE

a, b = length of sides of cooling fins, m
A = heat transfer area, m^2
A_r = heat conduction cross-section area (radius r), m^2
C = degrees centigrade
d = diameter circular cooling fin, m
D_b, D_h = diameter of base and fin hole, m
Φ = fin effectiveness: ratio fin to base admittance
h = heat transfer coefficient, w/m^2C (watts per square meter, C); see Appendix I
H, K = Hankel functions, real and imaginary argument
η = fin efficiency: admittance ratio, real fin to infinitely conductive fin
J, I = Bessel function, first kind, real and imaginary argument
k = thermal conductivity of fin material, w/mC
m = meter
Λ_e = normalized volume of fin, excluding center hole
Λ_i = normalized volume of fin, including center hole
ψ = thermal admittance function of cooling fin
q = heat flow, w
q_0 = heat flow at inner radius, w
q_1, q_2, q_3, q_4 = heat flow through lead, upper body, lower body, fin, w
r = radius of any segment in fin, m
r_0, r_1 = inner and outer fin radius, equivalent for analysis, m
$R=\sqrt{ks/2h}$ = natural radius, m
R_t, R_q = subtangents to temperature and heat curves, m
s = thickness of fin, m
S_t, S_q = tangents to temperature and heat curves, m
$w=r_1-r_0$ = width of fin, m
T = temperature rise over ambient, C
T_0, T_1 = temperature rise at inner and outer radius of fin, C
θ_1, θ_2 = integration constants, C
$u=r/R$ = normalized variable
V_e = volume of fin excluding center hole, m^3
V_i = volume of fin including center hole, m^3
w = watt
$Z=T/q$ = thermal impedance, C/w
Z_{a1}, Z_{a2}, etc. = external thermal impedances, C/w
Z_{b1}, Z_{b2}, etc. = internal thermal impedances, C/w
Z_d, Z_i, Z_f = equivalent lumped thermal impedances: device, internal-to-fin, fin, C/w
Z_{s1}, Z_{s2}, etc. = infinitesimal thermal impedances in series in fin, C/w
Z_{p1}, Z_{p2}, etc. = infinite thermal impedances in parallel to fin, C/w

Fig. 4(A) and (B) shows a device which is cooled by a square fin; its equivalent circular fin is shown in (C). The inner radius of the fin is given approximately by the mean value of the radii of the base of the device and the hole in the fin.

$$r_0=\frac{D_h+D_b}{4} \tag{1}$$

Fins with a pipe-thread hole have an inner radius equal to half the pitch diameter of the thread. The diameter of the device to be cooled is assumed known, hence the inner diameter r_0 of the fin is taken as reference diameter.

The external radius of the fin is determined by the following:

For a square, sides b, thickness s

$$r_1=\sqrt{\frac{b^2+2bs}{\pi}} \tag{2}$$

For a rectangle, sides a, b

$$r_1=\sqrt{\frac{ab+(a+b)s}{\pi}} \tag{3}$$

For a circular fin, diameter d

$$r_1=\frac{d}{2}\sqrt{1+\frac{2s}{d}} \tag{4}$$

For studying the heat transfer in Fig. 4(C) and with the foregoing dimensions, only the two faces of the fin which are shown by heavy solid lines are considered. For a first approximation the thickness of the fin in these equations may be neglected.

Heat Flow and Temperature Rise

Fig. 5(A) shows a cross section of the fin and (B) the curves of temperature and heat flow, plotted against the same radius. At an arbitrary distance from the center, the radial heat flow q passes through a cylindrical area A_r into the annual volume element dV, bounded by the radial increment dr. Heat conductivity k of the fin and heat transfer coefficient h to the ambient space are constant.

The temperature drop in the volume element dV is given by the law of conduction, as

$$dT=-\frac{q\,dr}{2\pi rsk} \tag{5}$$

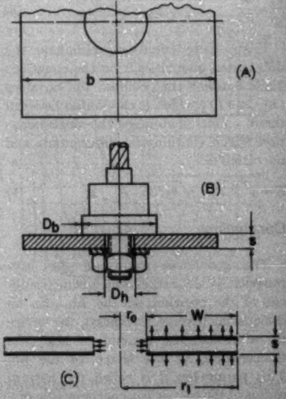

Fig. 4. Comparison of a real device and its cooling fin and the simplified fin for mathematical treatment

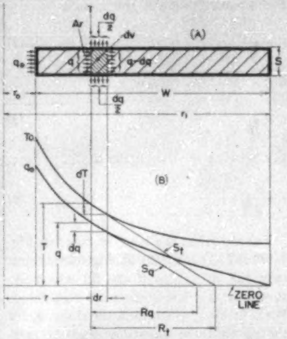

Fig. 5. Cross section of simplified fin and temperature: heat flow curves along a radius of the fin

Heat dissipated by the volume element is given by the law of heat transfer:

$$dq = -4\pi hTrdr \tag{6}$$

If in Fig. 5, the tangent S_t is drawn to the temperature curve (at the radius r), and the tangent Sq is drawn to the heat flow curve (as the same radius), the distances from the intersections of these tangents with the base line ($T=0$, $q=0$) to the radius r are defined as the subtangents R_t and Rq. By the similarity of triangles the following is obtained.

$$\frac{dT}{T} = \frac{dr}{R_t} \tag{7}$$

$$\frac{dq}{q} = \frac{dr}{R_q} \tag{8}$$

Using these equations, eliminate the differential quantities from the equations 5 and 6, which then contain the variables only as rT/q which is eliminated between them. Thus is obtained the single equation which contains no differentials and no variables:

$$R = \sqrt{R_tR_q} = \sqrt{ks/2h} \tag{9}$$

Conclusions

The geometric mean of the subtangents is a constant which is independent of the position on the fin, the fin dimensions (except thickness), the device to be cooled, the amount of heat, the temperature, or the shape of the fin. This parameter R is called the natural radius of the fin; it is a characteristic distance of a certain sheet material and heat transfer mode. For many investigations it is advantageous to normalize all dimensions with R and obtain equations which are dimensionless.

By observing the shape of the curves in Fig. 5, the following conclusions may be drawn: if the natural radius is much smaller than the fin width, temperature and heat flow decrease too rapidly to assure an adequate heat supply to the outer parts of the fin. On the other hand, if the natural radius is much larger than the fin width, temperature and heat flow decrease too little, and the fin is too thick. When designing cooling fins, it is advantageous first to determine a natural radius commensurate with the fin width to prevent unrealistic assumptions.

For constant values of thermal conductivity and heat transfer constants, the model law of cooling fins is that the thickness s varies with the square of the lineal dimensions, e.g., doubling the fin size means quadrupling the thickness if a proportional flow is expected.

Solution of the Differential Equations

Equations 5 and 6 may be combined into a single equation, containing either the temperature T or the heat flow q only. Equation 5 is rewritten and differentiated to

$$\frac{dq}{dr} = -2\pi ks\left(\frac{dT}{dr} + r\frac{d^2T}{dr^2}\right) \tag{10}$$

This derivative is also available from equation 6; it combines with 10 to form

$$\frac{d^2T}{dr^2} + \frac{1}{r}\frac{dT}{dr} - \frac{2h}{ks}T = 0 \tag{11}$$

This is a Bessel differential equation, order zero; the solution is shown in Appendix II. Temperature distance relationship is given there by equation 41 as a function of the normalized values: r/R, r_0/R and r_1/R.

In the most general case the reference radius r is the only variable but the parameters r_0, r_1 and R are unknown. Even when working with normalized variables (with respect to a yet undetermined value of R) there are still two unknown parameters. A general plot of the temperature-distance function therefore involves at least two independent parameters and one variable; this cannot be presented in one graph. For this reason only two specific examples are shown, in which the inside radius r_0 is held constant at 1 cm (centimeter) and the outside radii are 6.3 cm for Fig. 3(A) and 15.2 cm for (B). Both figures are plotted for several values of the natural radius R. Temperature-radius curves follow a common pattern: the temperature drop within the fin is highest near the inner radius and approaches zero at the outer radius. In Fig. 3(B), if the natural radius is increased from 16.7 cm to 50 cm, thus making the fin nine times heavier, the outer rim temperature increases from 50% to 90% of the inner rim temperature. In other words, 40% of temperature range is gained by the addition of 800% more material. To find an optimum of heat dissipation versus fin volume other concepts must be introduced which facilitate the comparison.

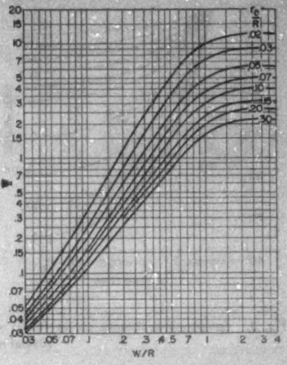

Fig. 6. Thermal admittance function of cooling fins plotted against ratio of fin width to natural radius and several ratios of inner to natural radii

Total heat dissipating capacity of the fin, for a certain temperature rise at the point of heat influx, may be found from equation 43 as

$$q_0 = 4\pi hr_0RT_0\psi \tag{12}$$

with

$$\psi = \frac{I_1\left(\frac{r_1}{R}\right)K_1\left(\frac{r_0}{R}\right) - I_1\left(\frac{r_0}{R}\right)K_1\left(\frac{r_1}{R}\right)}{I_0\left(\frac{r_0}{R}\right)K_1\left(\frac{r_1}{R}\right) - I_1\left(\frac{r_1}{R}\right)K_0\left(\frac{r_0}{R}\right)} \tag{13}$$

Define ψ as the thermal admittance function of the cooling fin; it indicates the ability of the fin to dissipate heat for a given inner radius, natural radius and temperature rise. All further discussion will be based on this function, which eliminates the necessity of using an unwieldy expression. Fig. 6 shows numerical values of the thermal admittance function for a wide range of values, expressed as fin width over natural radius and inner radius over natural radius. In this figure it is apparent that the ratio of fin width over natural radius is important; if it is larger than unity the thermal ad-

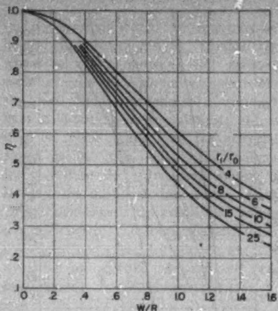

Fig. 7. Fin efficiency plotted against ratio of fin width to natural radius and several ratios of inner to natural radii

mittance is almost constant, no matter how wide the fin is made.

From equation 12 the thermal impedance of the fin is determined as

$$Z_f = \frac{T_0}{q_0} = \frac{1}{4\pi h r_0 R \psi} \tag{14}$$

With this equation and Fig. 6, the thermal impedance of any fin may be determined without much numerical work.

Fin Efficiency

The fin efficiency may be defined as the ratio of total heat dissipated by a cooling fin to heat dissipated by an identical fin of infinitely conductive material. It is a measure for the loss of heat dissipation capacity by the internal temperature drop of the fin.

Equation 12 gives the heat dissipated by the real fin. Heat dissipated by a fin of infinite conductivity may be expressed as

$$q_t = 2\pi(r_1^2 - r_0^2)hT_0 \tag{15}$$

$$\eta = \frac{q_0}{q_t} = \frac{2(R/r_0)\psi}{(r_1/r_0)^2 - 1} \tag{16}$$

Fig. 7 shows the efficiency plotted against the ratio of fin width over natural radius, for several values of outer to inner radii. The efficiency is greatly influenced by the relative fin width and, as in Fig. 6, it appears that relative widths of more than unity are not economical. Very low relative widths produce efficiencies close to unity, very desirable, of course, but also wasteful in material. Fig. 8 shows a plot of efficiency versus the ratios of natural over inner, and of outer over inner, radii. It covers a wide range with better accuracy than Fig. 7, though it is less informative at first sight. Knowing the efficiency one may calculate the heat dissipated by the fin as

$$q_0 = hA\eta T_0 \tag{17}$$

For noncircular fins, the efficiency may be approximated by selecting a safe (i.e., large) outer radius, then the real heat dissipation will be somewhat better than calculated.

In an investigation where any dimension, including the inner radius, may be changed, the concept of fin efficiency is most valuable, although it does not present an optimum value. When, however, the optimum curves (for constant inner radius of the fin) derived in Fig. 9(A) and (B) are compared with the curves for constant efficiency in Fig. 8, it is found that they follow very closely the constant efficiency curve of 0.5. At first sight this result is surprising because the mathematical derivation of the constant efficiency curve is not too difficult (from equation 16), whereas the derivation of the optimum curve defies direct analysis and must be made graphically. However, if this result is analyzed by the practical engineer, it is obvious, and it may be concluded that optimum fins have an efficiency of approximately 50% which corresponds to equal internal and external thermal impedances.

Fin Effectiveness

For fins with constant inner radius the concept of fin effectiveness is more useful than the fin efficiency. The ratio of heat dissipated by the cooling fin to the heat dissipated by the base area (inner radius) under the same conditions and for the same temperature rise is defined as fin effectiveness.

Again the reference value is fictive: It is part of an inseparable total, and the heat transfer constant (of the device alone) is different from the constant for the cooling fin. However, a close approximation may be found by assum-

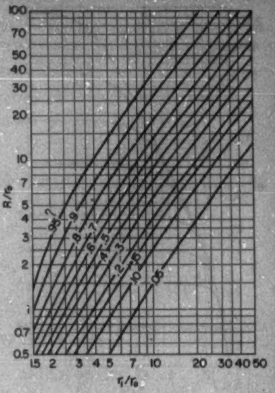

Fig. 8. Curves of constant fin efficiency plotted against ratios of outer over inner, and natural over inner, radii

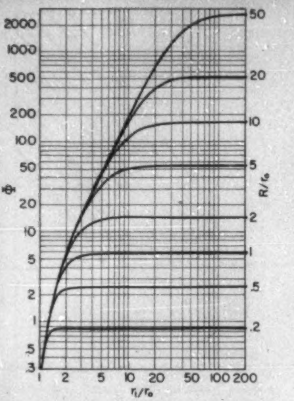

Fig. 10. Fin effectiveness plotted against ratio of outer to inner radii for several values of natural to inner radii

ing that the heat dissipated per unit area of the device is constant and by multiplying it by the computed ratio of heat transfer constants obtained from known information; see Appendix I.

If the heat is known which can be dissipated by the device alone, the heat q_b dissipated by the base area alone (equal heat transfer constant as the fin) may be determined. The heat q_0 to be dissipated by the fin is also known.

Fin effectiveness is

$$\Phi=q_0/q_b \tag{18}$$

Equation 12 gives the heat dissipated by the fin. Heat dissipated by the base area is

$$q_b=\pi r_0^2 h T_0 \tag{19}$$

Thus the fin effectiveness is

$$\Phi=4\left(\frac{R}{r_0}\right)\psi \tag{20}$$

Fin effectiveness and fin impedance is

$$\Phi Z_f=1/\pi r_0^2 h \tag{21}$$

Fig. 10 gives the curves of fin effectiveness against ratio of outer to inner radii for several ratios of natural to inner radii. The common ascendent curve on the left represents fins of infinite conductivity, flat branches of the curves to the right represent fins which are too thin to carry heat towards their outer areas.

In designing a new cooling fin, the thermal impedance Z_f which must be achieved is usually known. From equation 21 the desired effectiveness is obtained and Fig. 10 yields a certain number of possible ratios of dimensions, the ratio of natural over inner radius being almost independent of the ratio of outer to inner radius.

Another plot for the values of fin effectiveness is shown in Fig. 9(A) and (B). In these curves, the value of effectiveness is kept constant, i.e., each curve represents many fins which can perform the same cooling duty. Similarly, the figure contains also the curves of constant volume to permit direct comparison of fin effectiveness and volume. The fin volume is defined as V_t or V_e, either including or excluding the material punched out for the center hole.

$$V_t=\pi r_1^2 s=2\pi\frac{h}{k}r_0^4\left(\frac{r_1}{r_0}\right)^2\left(\frac{R}{r_0}\right)^2 \tag{22}$$

$$\begin{aligned}V_e&=\pi(r_1^2-r_0^2)s\\&=2\pi\frac{h}{k}r_0^4\left[\left(\frac{r_1}{r_0}\right)^2-1\right]\left(\frac{R}{r_0}\right)^2\end{aligned} \tag{23}$$

Per-unit fin volume (Δ_t including, Δ_e excluding center hole) is defined as

$$\Delta_t=\frac{V_t k}{2\pi h r_0^4}=\left(\frac{r_1}{r_0}\right)^2\left(\frac{R}{r_0}\right)^2 \tag{24}$$

$$\Delta_e=\frac{V_e k}{2\pi h r_0^4}=\left[\left(\frac{r_1}{r_0}\right)^2-1\right]\left(\frac{R}{r_0}\right)^2 \tag{25}$$

These values are only representative as long as the inner radius is constant; if it varies, the volume is proportional to the ratio Δ times the fourth power of the inner radius. In Fig. 9(A), fin effectiveness and per-unit volume are plotted against the same ratios of radii as in Fig. 8. It is immediately apparent that the curves of fin efficiency and fin effectiveness are almost perpendicular to each other in the area of greatest usefulness. Wherever the curves of constant fin effectiveness and constant volume are parallel to each other, there is a minimum of volume and maximum of effectiveness. This, then, represents a true optimum point for a given value of effectiveness (regardless as to whether it is economical to strive for such an effectiveness). Connecting the optima together gives the dashed line in Fig. 9(A) and (B); in the latter the only difference is the exclusion of the center hole from the fin volume.

The dashed optimum lines in Figs. 9(A) and (B) give a preferred connection between the ratios of outer to inner and natural to inner radii, establishing simultaneously the fin effectiveness and volume. It is interesting that the influence of the center hole is very small, the optimum curves in (A) and (B) being almost identical; (A) is more interesting from the standpoint of material cost, and (B) from the standpoint of weight. Curves in these two figures are deleted in the upper left-hand corner because the basic assumption of thin fins is invalid.

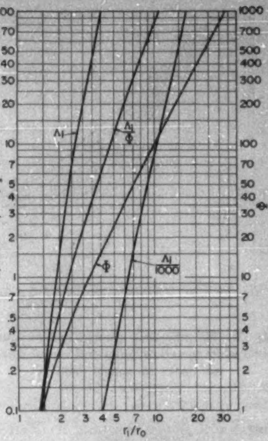

Fig. 11. Per-unit fin volume, fin effectiveness and ratio of volume over effectiveness along optimum curve of Fig. 9(A), plotted against ratio of outer to inner radii

Fig. 11 shows the curves of normalized volume and effectiveness plotted against the ratio of outer to inner radii, along the optimum curve of Fig. 9(A); hence these values are correct only for the ratios of dimensions established by the dashed line in 9(A). Forming the ratio of fin volume over effectiveness gives

$$\frac{\Delta_t}{\Phi}=\frac{k}{2r_0^2}V_t Z_f=\frac{1}{4\psi}\left(\frac{r_1}{r_0}\right)^2\left(\frac{R}{r_0}\right) \tag{26}$$

This ratio may be defined as a "figure of demerit;" it indicates how much material is needed to achieve a certain effectiveness (the inner radius and conductivity unchanged). Surprisingly, this figure of demerit increases rapidly with increasing ratio of outer to inner radii and hence increasing effectiveness.

Conclusions

Fins are much more wasteful in material if they are wide; in the range of practical usefulness the volume increases approximately with the third power of the ratio of radii and the power 4/3 of the effectiveness. Also, many narrow fins are much lighter than one wide fin.

Unfortunately, this conclusion conflicts with the realities of present design and applications, but this insight may be helpful in future designs, particularly where saving of material and space is essential. In multiple-fin arrangements the mass of material required to conduct heat from the device to a plurality of fins may be much higher than the material saved in the fins. Economic analysis incorporating this additional volume is beyond the scope of this paper; it is, easily performed by using the values available herein, in conjunction with other considerations given by the device, the available space, and the preferred proportions.

Appendix I. Heat Conductivity and Heat Transmission

Heat conductivity k for some metals in w/mC (approximately) is as follows:

Copper, 370
Aluminum, 200
Brass, 100
Mild steel, 45

Heat transmission may be analyzed as follows.

Radiation:

h_r in (w/m^2C), ϵ = emissivity

$$h_r=5.71\,10^{-8}\epsilon\left(\frac{T_1^4-T_2^4}{T_1-T_2}\right)$$

$$T_a=\frac{T_1+T_2}{2};\quad T_g^2=\frac{T_1^2+T_2^2}{2};\quad T_g\simeq T_a$$

$$h_r=2.28\,10^{-7}\epsilon T_aT_g^2\simeq 2.28\,10^{-7}\epsilon T_a^3$$

Note: T_1, T_2, T_a, T_g are expressed in degrees Kelvin

The foregoing is valid only if radiation is not obstructed by other hot bodies (cooling fins).

Free convection (in air at sea level):

h_c in w/m^2C, approximately

$$h_c=1.4\left(\frac{\Delta T}{L}\right)^{1/4}$$

where

ΔT = temperature difference metal-air, C
L = height of fin in meters (or length of flow along fin)

Forced cooling (in air):

h_f in w/m^2C

$$h_f=0.055\frac{k_a}{L^{1/4}}\left(\frac{V}{\nu}\right)^{3/4}$$

T (C)	100 k_a	$10^5\,\nu$
20	2.6	1.5
60	2.9	1.9
100	3.2	2.4
140	3.5	2.8

where

k_a = thermal conductivity of air, w/mC
ν = cinematic viscosity, m^2/s
V = air velocity, m/s

Minimum fin spacing is approximately two thicknesses of boundary layer b, or slightly less:

$$b=5.83\sqrt{\frac{\nu L}{V}}$$

Appendix II. Solutions of Equations

Introduce the new variable $u=r/R$, and insert it into equation 11:

$$u=r/R \tag{27}$$

and insert it into equation 11:

$$\frac{d^2T}{du^2}+\frac{1}{u}\frac{dT}{du}-T=0 \tag{28}$$

Solutions of this equation are Bessel and Hankel functions with imaginary arguments. To simplify the equations, use the following notations:

$$J_p(x)=\frac{\left(\frac{x}{2}\right)^p}{p!}\sum_{k=0}^{\infty}\frac{p!}{k!(p+k)!}\left(\frac{ix}{2}\right)^{2k} \tag{29}$$

$$H_p^{(1)}(x)=\frac{i}{\sin px}[e^{-p\pi i}J_p(x)-J_{-p}(x)] \tag{30}$$

$$I_0(x)=J_0(ix) \tag{31}$$

$$K_0(x)=H_0^{(1)}(ix) \tag{32}$$

$$I_1(x)=-iJ_1(ix) \tag{33}$$

$$K_1(x)=-iH_1^{(1)}(ix) \tag{34}$$

$$\frac{dI_0(x)}{dx}=I_1(x) \tag{35}$$

$$\frac{dK_0(x)}{dx}=K_1(x) \tag{36}$$

The general solution of equation 28 is

$$T=\theta_1I_0\left(\frac{r}{R}\right)+\theta_2K_0\left(\frac{r}{R}\right) \tag{37}$$

Substitute in equation 5

$$q=-\frac{2\pi rsk}{R}\left[\theta_1I_1\left(\frac{r}{R}\right)+\theta_2K_1\left(\frac{r}{R}\right)\right] \tag{38}$$

The integration constants θ_1 and θ_2 are determined by the boundary conditions

$r=r_0$: $T=T_0$ and $q=q_0$

$r=r_1$: $q=0$

Hence, the following is obtained:

$$\theta_1=\frac{T_0K_1\left(\frac{r_1}{R}\right)}{I_0\left(\frac{r_0}{R}\right)K_1\left(\frac{r_1}{R}\right)-I_1\left(\frac{r_1}{R}\right)K_0\left(\frac{r_0}{R}\right)} \tag{39}$$

$$\theta_2=\frac{T_0I_1\left(\frac{r_1}{R}\right)}{K_0\left(\frac{r_0}{R}\right)I_1\left(\frac{r_1}{R}\right)-K_1\left(\frac{r_1}{R}\right)I_0\left(\frac{r_0}{R}\right)} \tag{40}$$

Inserting these constants into equations 37 and 38 yields

$$T=T_0\left[\frac{I_0\left(\frac{r}{R}\right)K_1\left(\frac{r_1}{R}\right)-K_0\left(\frac{r}{R}\right)I_1\left(\frac{r_1}{R}\right)}{I_0\left(\frac{r_0}{R}\right)K_1\left(\frac{r_1}{R}\right)-K_0\left(\frac{r_0}{R}\right)I_1\left(\frac{r_1}{R}\right)}\right] \tag{41}$$

$$q=4\pi hrRT_0\times\left[\frac{I_1\left(\frac{r_1}{R}\right)K_1\left(\frac{r}{R}\right)-I_1\left(\frac{r}{R}\right)K_1\left(\frac{r_1}{R}\right)}{I_0\left(\frac{r_0}{R}\right)K_1\left(\frac{r_1}{R}\right)-I_1\left(\frac{r_1}{R}\right)K_0\left(\frac{r_0}{R}\right)}\right] \tag{42}$$

and the initial heat flow into the fin

$$q_0=4\pi hrRT_0\times\left[\frac{I_1\left(\frac{r_1}{R}\right)K_1\left(\frac{r_0}{R}\right)-I_1\left(\frac{r_0}{R}\right)K_1\left(\frac{r_1}{R}\right)}{I_0\left(\frac{r_0}{R}\right)K_1\left(\frac{r_1}{R}\right)-I_1\left(\frac{r_1}{R}\right)K_0\left(\frac{r_0}{R}\right)}\right] \tag{43}$$

Discussion

I. K. Dortort (I-T-E Circuit Breaker Company, Philadelphia, Pa.): The curves presented in this paper should be very helpful in designing cooling fins in which the heat flow is generally radial. A fuller treatment of forced air cooling, even though much less rigorous, would make the paper more useful. Since the heat transfer to air controls the "natural radius," a great deal of work must be done before the curves given in the paper can be used. This is not the fault of the author, but of the existing literature.

The authors undoubtedly had good reason for using the meter instead of the centimeter as the unit of length. Having chosen the meter, however, its use should have been made consistent throughout the paper to avoid confusion. Special care must be taken in applying heat transfer data from other sources to equations in Appendix II.

In their conclusion, the authors emphasize the fact that extended cooling surfaces consisting of many narrow fins require less material than one large fin, although other economic factors will influence the final design. The authors mention that one of the objections to multiple fins is the amount of material required at the hub to transmit heat from the semiconductor to the multiple fins. It should be noted that this mass of material need not be wasted if it is used both for heat transmission to the fins and as the electric bus. In this arrangement the fins are attached to the sides of a bus bar on which all parallel cells are mounted. This has permitted us to take full advantage of paralleling busses, voltage divider transformer circuits, and compact current-balancing reactors. A large forced air-cooled semiconductor rectifier of this design has been found economical in material, labor, and space.

Forward Current Surge Failure in Semiconductor Rectifiers

F. E. GENTRY
ASSOCIATE MEMBER AIEE

THE APPLICATION of semiconductor rectifiers to most practical circuits requires a knowledge of the device's ability to withstand the forward current surges encountered as a result of severe faults or high instantaneous overloads. In particular, an understanding of the nature of failure is desirable in order to properly protect the rectifier. Suitable fuses can then be chosen to obtain optimum utilization of the rectifier. Gutzwiller[1] has developed fuse-selection techniques which are adequate for this purpose.

The purpose of this paper is to establish a better understanding of forward current surge failure. In particular, surge failure as a function of current and time is investigated for times less than 10 milliseconds.

Mechanism of Failure

Forward current surge failure can usually be attributed to melting of the semiconductor or the materials to which it is attached. This occurs when the semiconductor reaches high enough temperature for the junction to melt and thus be damaged or destroyed. Fig. 1 shows a microsectioned[2] junction which melted as a result of the application of a half-sine-wave surge of 8.3-millisecond duration. In this case both the base contact and junction solders alloyed with the silicon to form a metallic short circuit through the rectifying junction.

Both forward and reverse current contribute to the temperature rise. The reverse heating is indirect in that the forward surge must raise the semiconducting material to a temperature sufficiently high for the reverse power to make a significant contribution to the total heat generated. When this contribution is such that the temperature continues to rise after the application of reverse voltage, the unit will thermally run away. This sequence is expected since reverse current increases exponentially with increasing temperature. The magnitude of the heat generated is determined by the forward and reverse voltage-current characteristic, the junction temperature, reverse voltage, junction area, surge current, and the thermal properties of the semiconductor and adjoining materials.

In addition to failure because of melting two other types of failure occur occasionally. In particular, if the semiconductor is prestressed as a consequence of poor design or fabrication techniques, the additional thermal stresses resulting from the high-temperature gradients caused by the surge may result in fracture. Proper mounting to minimize stress has been discussed by Henkels.[3] Severe damage which cannot be explained by either melting or fracture sometimes occurs because of breakdown on the surface of the semiconductor. It is suspected that this type of failure is caused by contamination, since these units can usually be recovered by suitable surface cleaning.

Nomenclature

T = temperature rise above steady-state temperature, C (degrees centigrade)
T_M = temperature necessary to melt the rectifying junction or cause transient thermal runaway, C
T_J = steady-state junction temperature, C
t = duration of surge, seconds
x = distance from junction, inches
k = thermal conductivity, (watt-inch)/(inch^2 C)
c_p = specific heat, (watt-second)/(pounds C)
ρ = density, pounds/inch^3
$\alpha = k/c_p$ thermal diffusivity, inch^2/second
$G(t)$ = heat per unit volume, watts/inch^3
l = length of middle zone, inch
R = resistance of middle zone, ohms
I = rms value of current, amperes
V = instantaneous voltage, volts
A_J = area of junction, inches^2
v = effective volume of semiconductor, inch^3
i = instantaneous current, amperes

subscripts
1 = material 1
2 = material 2

Analysis of Failure

MELTING

For melting to occur the semiconductor must reach a temperature which will cause it or the adjacent materials to melt and damage or destroy the junction. Consequently, the problem becomes one of determining how this temperature is related to current, time, and the device parameters. Diebold[4] has considered this problem for the case where heat is generated only at the junction. For current densities in excess of 1,000 amperes/centimeter^2 an appreciable voltage drop also occurs across the middle zone of the rectifier. Kleinman,[5] Hall,[6] and Sah, Noyce, and Shockey[7] have predicted this drop. However, the exact equations will be approximated because their complexity prohibits their use in this analysis.

Using the model shown in Fig. 2, the voltage drop is considered to consist of three parts:

V_J = voltage drop across the junction
V_m = voltage drop across the middle zone of the rectifier
V_e = voltage drop caused by the resistance of the materials not included in regions *1* and *2*

V_e is subtracted for this analysis since the heat produced in the materials other than the semiconductor and its junction is

7—Ohmic resistance (from counterelectrodes to external connections)

relatively small and has little effect on the temperature rise of the junction. The drop across the semiconductor then becomes V_J+V_m.

As a first approximation the resistance of the middle zone is considered to be constant. The voltage drop across the middle zone is then iR, with the remainder of the drop occurring at the junction. The total drop then becomes V_J+iR. If this equation is fitted to a typical rectifier curve as shown in Fig. 3, a good approximation is realized if V_J is assumed to be constant. The heat generated then becomes $Vi=V_Ji+i^2R$, where V_Ji is the heat generated at the junction and i^2R is the heat generated in the middle zone.

For very short times the model shown in Fig. 4 can be used. The peak junction temperature rise for a rectangular current pulse is then determined and set equal to T_M; see Appendix I. This leads to the equation

$$\frac{R\sqrt{\alpha_1}}{l_1}(I^2t)+\frac{2V_J}{\sqrt{\pi}}(\sqrt{I^2t})-A_J(T_M-T_J)\left(\frac{k_2}{\sqrt{\alpha_2}}+\frac{k_1}{\sqrt{\alpha_1}}\right)=0 \quad (10)$$

Failure will occur when the junction reaches the destructive temperature T_M. Examination of the equation reveals that for a fixed set of rectifier parameters, a solution is $I^2t=C_1$, a constant. This means that for failure to occur the product I^2t must exceed C_1. To obtain an insight into the effect the current waveshape would have on the solution, a similar analysis was made using a ramp function for the current waveshape. This solution was found to be

$$\frac{R\sqrt{\alpha_1}}{l_1}(I^2t)+\frac{4V_J}{\sqrt{3\pi}}(\sqrt{I^2t})-A_J(T_M-T_J)\left(\frac{k_2}{\sqrt{\alpha_2}}+\frac{k_1}{\sqrt{\alpha_1}}\right)=0$$

Further calculations (see Appendix II) show these solutions to be reasonable for $t<l^2/\alpha$. For typical silicon and germanium rectifiers now in production the time l^2/α is:

$l^2/\alpha=500$ microseconds for silicon
$l^2/\alpha=4$ milliseconds for germanium

Using equation 10, calculations are compared with experimental results for a silicon rectifier; see Fig. 5 and Appendix III.

For longer times a distributed constant model becomes rather difficult to analyze and it is convenient to use a model with lumped parameters, as shown in Fig. 6, for further study. For times longer than 10 milliseconds most surge currents are usually repetitive pulses. As a result, analytical study is considerably more difficult. However, the problem is particularly adaptable to solution using an electrical analog of the thermal circuit. The effect of reverse heating, change in characteristics, and complex waveshapes could also be considered by using feedback in the analog.

Fig. 4. Model used for mathematical analysis

An analytical study using a more refined model, in which a finite solid with internal heat generation and heat generated at one face is bounded on each side by an infinite slab, has been conducted. However, this solution is not included in this paper.

Fracture

For fracture to occur the semiconductor material must be strained beyond its yield point. If the built-in stresses plus the stresses set up by the temperature gradient resulting from the surge reach a critical value S_c, the yield point will be exceeded and the semiconductor will fracture. The temperature gradient is determined by differentiating equation 6 and evaluating it at $x=0$; see Appendix IV. The result is

$$I^4t \approx \left[\frac{C_3 l A_J \sqrt{\pi} k_1 (k_2\sqrt{\alpha_1}+k_1\sqrt{\alpha_2})}{2Rk_2\alpha_1}\right]^2 \qquad (15)$$

This equation states that for a fixed set of rectifier parameters, failure should occur when the product I^4t exceeds the value found by solving the foregoing equation for I^4t.

Experimental Procedure

The units used to establish the experimental points in Fig. 5 were selected from the same production lot and were matched in the forward direction to assure uniform results. Their junction area was approximately 5×10^{-4} inch². The tests shown in Fig. 5 were conducted at 25 C with no load and no reverse voltage applied in order to simulate the conditions used in the mathematical analysis. After each surge the units were checked for reverse characteristic degradation and were considered to be failures if the reverse current exceeded 5 microamperes at rated voltage. In general, the units showed no degradation until the surge current was within 10% of that necessary to cause catastrophic failure.

The basic circuits for generation of the current pulses are shown in Figs. 7 and 8. The circuit shown in Fig. 7 permits the application of steady-state load current and reverse voltage when needed. In addition, any desired number of repetitive pulses can be obtained with a suitable timer. For shorter time pulses the circuit shown in Fig. 8 was used. The inductance was necessary for shaping the current into half-sine-wave pulses. All experimental values of current were converted to rms values for comparison with the calculated data. Voltage and current measurements during the surge were made using peak-reading voltmeters with a response time of 2 microseconds.

The experimental points for the forward voltage-current curve shown in Fig. 3 were taken using a 300-microsecond current pulse. The values indicated are peak values.

General Observations

Surge failure in germanium and silicon rectifiers normally results in the junction being short-circuited. However, if the the magnitude or duration of the surge current becomes several times greater than that of the failure point, vaporization of materials may occur, causing the unit to open the circuit or even explode. For times less than 8 milliseconds, most germanium and silicon rectifiers tested by the author fail when the product $I^2t = C_1$ is exceeded, where C_1 is a constant determined by rectifier design and steady-state junction temperature. With presently available designs the temperature rise necessary to cause failure is somewhat lower for germanium than for silicon rectifiers. Consequently the effect of initial junction temperature is much more pronounced for germanium than for silicon devices.

For germanium and silicon rectifiers, the resistive portion of the forward characteristic increases with increasing temperature. When a surge of forward current is applied the heat generated in the middle zone increases as the tempera-

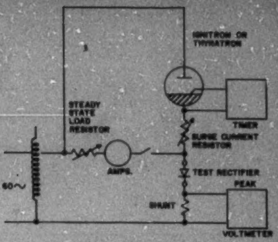

Fig. 7. Basic circuit for generating one or more current surges of 8.3-millisecond duration

ture of the semiconductor rises. This phenomenon is probably a controlling factor in determining the surge failure point.

Conclusions

Surge current failure in germanium and silicon rectifiers is usually the result of very high temperature rise within the semiconductor. Severe damage of the junction then causes the unit to short-circuit itself by localized melting of the semiconductor or its adjacent contacts.

The failure point is dependent on the rectifier design, initial junction temperature, reverse voltage, and the magnitude, shape, and duration of the applied surge current. In general, for surges of less than 1-millisecond duration, germanium and silicon rectifiers fail when the product I^2t exceeds a constant value dependent on the design and characteristics. For longer periods of time materials other than those immediately adjacent to the semiconductor become significant and alter the surge characteristics.

Failure due to fracture should occur when the product I^2t exceeds a constant value dependent on the design and characteristics. However, this mechanism of failure was not observed in the rectifiers tested.

Appendix I

Consider the two adjacent semi-infinite solids shown in Fig. 4. The equation[8] describing the flow of heat in these materials is

$$\frac{\partial T(t,x)}{\partial t}=\alpha\frac{\partial^2 T(t,x)}{\partial x^2}+\frac{G(t)}{\rho c_p} \tag{1}$$

with the initial and boundary conditions

$$T_1(0,x)=T_2(0,x)=\frac{\partial T_1(t,\infty)}{\partial x}=\frac{\partial T_2(t,-\infty)}{\partial x}=0$$

$$k_2\frac{\partial T_2(t,0)}{\partial x}-k_1\frac{\partial T_1(t,0)}{\partial x}=\frac{IV_J}{A_J}$$

and the assumptions

$$G_1(t)=\frac{I^2R}{v_1}$$

$$G_2(t)=0$$

Solving by Laplace transforms gives, for material 2,

$$\frac{\partial^2 T_2(s,x)}{\partial x^2}-\frac{s}{\alpha_2}T_2(s,x)+\frac{T_2(0,x)}{\alpha_2}+\frac{G_2(s)}{\rho_2 c_{p2}}=0 \tag{2}$$

Since

$$G_2(s)=0$$

$$T_2(0,x)=0$$

$$\frac{\partial T_2(s,-\infty)}{\partial x}=0$$

then

$$T_2(s,x)=B\epsilon^{\sqrt{s/\alpha_2}\,x} \tag{3}$$

For material 1,

$$\frac{\partial^2 T_1(s,x)}{\partial x^2}-\frac{sT_1(s,x)}{\alpha_1}+\frac{T_1(0,x)}{\alpha_1}+\frac{G_1(s)}{\alpha_1\rho_1 c_{p1}}=0 \tag{4}$$

Since

$$G_1(s)=\frac{I^2R}{sv_1}$$

$$T_1(0,x)=0$$

$$\frac{\partial T_1(s,\infty)}{\partial x}=0$$

then

$$T_1(s,x)=C\epsilon^{-\sqrt{s/\alpha_1}\,x}+\frac{I^2R}{s^2\rho_1 c_{p1}v_1} \tag{5}$$

At the boundary between materials 1 and 2

$$k_2\frac{\partial T_2(s,0)}{\partial x}-k_1\frac{\partial T_1(s,0)}{\partial x}=\frac{V_JI}{sA_J}$$

and $T_1(s,0)=T_2(s,0)$

Therefore

$$T_1(s,x)=\frac{1}{\left(\frac{k_2}{\sqrt{\alpha_2}}+\frac{k_1}{\sqrt{\alpha_1}}\right)}\times\left(\frac{V_JI}{s^{3/2}A_J}-\frac{I^2Rk_2}{s^2\rho_1c_{p1}v_1\sqrt{\alpha_2}}\right)\epsilon^{-\sqrt{s/\alpha_1}\,x}+\frac{I^2R}{s^2\rho_1c_{p1}v_1} \tag{6}$$

Transforming to a function of t gives

$$T_1(t,x)=\frac{1}{\left(\frac{k_2}{\sqrt{\alpha_2}}+\frac{k_1}{\sqrt{\alpha_1}}\right)}\frac{V_JI}{A_J}\times\left(2\sqrt{\frac{t}{\pi}}\,\epsilon^{-\frac{x^2}{4\alpha_1 t}}-\frac{x}{\sqrt{\alpha_1}}\operatorname{erfc}\frac{x}{2\sqrt{\alpha_1 t}}\right)-\frac{I^2Rk_2}{\sqrt{\alpha_2}\rho_1c_{p1}v_1}\int_0^t\operatorname{erfc}\frac{x}{2\sqrt{\alpha_1\tau}}\,d\tau+\frac{I^2Rt}{\rho_1c_{p1}v_1} \tag{7}$$

At the interface $x=0$ the temperature is

$$T_1(t,0)=\frac{1}{\left(\frac{k_2}{\sqrt{\alpha_2}}+\frac{k_1}{\sqrt{\alpha_1}}\right)}\times\left(\frac{2V_J}{A_J\sqrt{\pi}}\sqrt{I^2t}+\frac{Rk_1I^2t}{\rho_1c_{p1}v_1\sqrt{\alpha_1}}\right) \tag{8}$$

or

$$T_1(t,0)=\frac{1}{A_J\left(\frac{k_2}{\sqrt{\alpha_2}}+\frac{k_1}{\sqrt{\alpha_1}}\right)}\times\left(\frac{2V_J\sqrt{I^2t}}{\sqrt{\pi}}+\frac{R\sqrt{\alpha_1}I^2t}{l_1}\right) \tag{9}$$

where R/l_1 is the resistance per unit length in material 1. When $T_1(t,0)=T_m-T_J$, the equation becomes

$$\frac{R\sqrt{\alpha_1}}{l_1}(I^2t)+\frac{2V_J}{\sqrt{\pi}}(\sqrt{I^2t})-A_J(T_M-T_J)\left(\frac{k_2}{\sqrt{\alpha_2}}+\frac{k_1}{\sqrt{\alpha_1}}\right)=0 \tag{10}$$

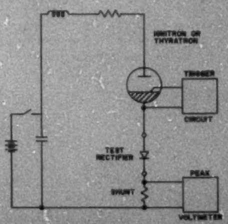

Fig. 8. Basic circuit for generating current surges of less than 5-millisecond duration

Appendix II

To determine the period of time for which the semi-infinite solution is valid, the solution for constant heat into the face of a finite slab is compared with that for a semi-infinite slab. These two solutions are developed by Carslaw and Jaeger.[8] At the face of the slabs the temperatures are: for the semi-infinite slab,

$$T_I=\frac{VI}{k}\left(\frac{2\sqrt{\alpha t}}{\sqrt{\pi}}\right)$$

for the finite slab,

$$T_F=\frac{VIl}{k}\left[1-\frac{8}{\pi^2}\sum_{n=0}^{\infty}\frac{\epsilon^{-\frac{\alpha\pi^2(2n+1)^2t}{4l^2}}}{(2n+1)^2}\right]$$

The ratio T_I/T_F is shown in Fig. 9. It is evident that the semi-infinite solution is a reasonably good approximation to the finite solution until t approaches l^2/α.

Appendix III

Using equation 10 and rectifier parameters taken from one of the silicon rectifiers used to establish the experimental characteristic curve in Fig. 3, a theoretical surge-failure curve can be predicted (see Fig. 5). The temperature T_M was chosen to be 660 C since at this temperature the aluminum adjoining the junction should melt sufficiently to cause damage. The following values were used to establish the calculated curve:

$V_J=1.1$ volts
$R=0.085$ ohm
$\alpha_1=0.073$ inch²/second
$\alpha_2=0.14$ inch²/second
$k_1=2.1$ (watt-inch)/(inch² C)
$k_2=5.6$ (watt-inch)/(inch² C)
$A_J=5.0\times10^{-4}$ inch²
$T_J=25$ C
$T_M=660$ C
$l=0.005$ inch

Substituting these values into equation 10 gives

$$4.6I^4t+1.24\sqrt{I^4t}-7.24=0$$

and solving for I^4t gives

$$I^4t=1.27$$

This value is somewhat lower than that obtained by experiment. This discrepancy can be accounted for, since the rectifiers used to establish the experimental curve were not one dimensional and diffusion of heat into other areas of the silicon pellet would occur.

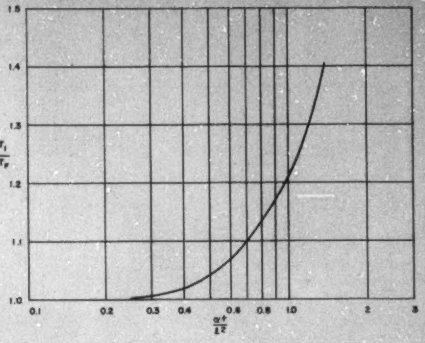

Fig. 9. Ratio of temperature rises for constant heat into face of infinite and finite slabs

Appendix IV

To determine how current and time affect the stresses in the semiconductor the temperature gradient must be obtained. Differentiating equation 6 gives

$$\frac{\partial T(s,x)}{\partial x}=\frac{1}{\left(\frac{k_2}{\sqrt{\alpha_2}}+\frac{k_1}{\sqrt{\alpha_1}}\right)}\times \left(\frac{-V_JI}{sA_J\sqrt{\alpha_1}}+\frac{I^2Rk_2}{s^{3/2}\rho_1c_{p1}v_1\sqrt{\alpha_1\alpha_2}}\right)\epsilon^{-\sqrt{s/\alpha_1}\,x} \tag{11}$$

Taking the inverse transform gives

$$\frac{\partial T_1(t,x)}{\partial x}=\frac{1}{\left(\frac{k_2}{\sqrt{\alpha_2}}+\frac{k_1}{\sqrt{\alpha_1}}\right)}\times \left[-\frac{V_JI}{A_J\sqrt{\alpha_1}}\operatorname{erfc}\frac{x}{2\sqrt{\alpha_1t}}+\frac{2I^2Rk_2}{\rho_1c_{p1}v_1\sqrt{\alpha_1\alpha_2\pi}}\left(\sqrt{t}\epsilon^{-\frac{x^2}{4\alpha_1t}}-\frac{x}{\sqrt{\alpha_1}}\operatorname{erfc}\frac{x}{2\sqrt{\alpha_1t}}\right)\right] \tag{12}$$

At $x=0$

$$\frac{\partial T(t,0)}{\partial x}=-\frac{1}{A_J\left(\frac{k_2}{\sqrt{\alpha_2}}+\frac{k_1}{\sqrt{\alpha_1}}\right)}\times \left(-\frac{V_JI}{\sqrt{\alpha_1}}+\frac{2R}{l\sqrt{\pi}}\frac{k_2\sqrt{\alpha_1}}{k_1\sqrt{\alpha_2}}\sqrt{I^4t}\right) \tag{13}$$

When

$$\frac{\partial T_1(t,0)}{\partial x}=C_2$$

where C_2 is the temperature gradient which results in the yield point being exceeded, then

$$C_2\approx\frac{2R}{lA_J\sqrt{\pi}}\times\frac{k_2\sqrt{\alpha_1}}{k_1\sqrt{\alpha_2}\left(\frac{k_2}{\sqrt{\alpha_2}}+\frac{k_1}{\sqrt{\alpha_1}}\right)}\times\sqrt{I^4t} \tag{14}$$

or

$$I^4t\approx\left[\frac{C_2lA_J\sqrt{\pi}k_1(k_2\sqrt{\alpha_1}+k_1\sqrt{\alpha_2})}{2Rk_2\alpha_1}\right]^2 \tag{15}$$

The Current-Limiting Fuse as Fault Protection for Semiconductor Rectifiers

F. W. GUTZWILLER
ASSOCIATE MEMBER AIEE

THE RAPID DEVELOPMENT of germanium and silicon power rectifier components in recent years has posed unique problems in fault current protection. These two types of rectifiers are characterized by the extremely high current densities tolerable in the active rectifying element at normal loads while maintaining low forward-voltage drop and thus high efficiency. For comparison purposes, full-load current densities (amperes per unit, cross-sectional area) in germanium and silicon rectifiers are approximately 1,000 times greater than in selenium and copper oxide metallic rectifiers.

The Semiconductor Rectifier Under Fault Conditions

The advantage of high continuous current ratings in a small package produces a handicapping corollary: limited thermal capacity of the rectifying element, the semiconductor p-n junction. When a constant load current is applied to a semiconductor rectifier, the temperature of the junction rises and stabilizes within a matter of cycles (at most, perhaps, seconds) at essentially a fixed temperature differential above the temperature of the heat sink to which the junction is attached.

In a similar manner, junction temperatures climb very quickly when overloads are impressed on the cell. Under fault conditions during which currents ranging from a few times to several hundred times normal load values may be expected, junction temperatures may skyrocket to destructive values within a few milliseconds or less. Immediate cell failure will occur as materials in and surrounding the junction melt under intensive local heating.[1] To prevent cell failure under these conditions, either the fault currents must be interrupted very quickly or rectifier components must be drastically derated.

The Current-Limiting Fuse

The current-limiting fuse, developed initially for protection of low-voltage branch feeder circuits connected to stiff systems, is admirably suited for interrupting potentially high fault currents quickly. From a thermal standpoint, current-limiting fuse construction is very similar to a germanium or silicon rectifier. The typical current-limiting fuse consists essentially of a fusible element of high current density, with low thermal capacity connected thermally and electrically to a heat sink of lower current density. This similarity in thermal construction between the current-limiting fuse and the semiconductor rectifier leads to similar thermal characteristics, and thus similar reactions to fault currents up to the point of melting in the case of the fuse and failure in the case of the rectifier cell.

In this paper, the term "current-limiting fuse" applies to a fuse which, when used within its current-limiting ratings, limits the peak let-through current to a value lower than that which would otherwise flow in the circuit, including the impedance of the fuse. It will also limit the clearing time to less than the duration of the first major current loop. The action of a typical current-limiting fuse is indicated in Fig. 1. The dashed line indicates the manner in which fault current would develop without the limiting action of the current-limiting fuse. If permitted to flow in a typical semiconductor rectifier circuit, the rectifier cells might be destroyed before the current reached zero the first time. However, at some point *A*, the current-limiting fuse link melts and the fuse commences to arc. Depending on the fuse design and the external circuit, the current may continue to rise somewhat further to point *B*, the peak let-through current. Beyond this point, the increasing impedance of the arcing fuse forces the fault current down to zero at some point *C*.

The industry refers to the region from fault initiation to *A* as melting time, and from *A* to *C* as arcing time. The sum of melting and arcing times (initiation to point *C*) is designated as clearing time.

This discussion will be limited to time intervals in this region below approximately one cycle where current-limiting fuses are effective. Protection for these time intervals is essential whenever d-c bus faults or cell failures can occur on relatively stiff electrical systems and when good rectifier cells are not considered expendable under these circumstances. In general, systems may be considered stiff for these purposes when the system impedance permits fault currents in excess of seven to ten times normal load current to flow. For faults and overloads at lower current levels, protection which acts more slowly (conventional fuses and circuit breakers) may generally be used.

Co-ordinating Rectifier Cell and Fuse

As shown by Gentry,[1] the forward-current capability of semiconductor power rectifiers in the subcycle region assumes an essentially constant $\int i^2dt$ characteristic at times under a critical value, which depends on the specific cell design. At times over this critical value, the constant minimum $\int i^2dt$ or I^2t value is conservative. (I=rms amperes, t=seconds.)

Current-limiting fuses exhibit a similar constant I^2t relationship. At less than approximately 0.01 second, current-limiting fuses melt at essentially constant I^2t.[2] Fuses may also be rated in terms of maximum clearing I^2t.[3]

Unfortunately, maximum clearing I^2t ratings are available on only a very limited number of types of current-limiting fuses at the time of this writing.[3] Until the

Paper 58-928, recommended by the AIEE Semiconductor Metallic Rectifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 13, 1958; made available for printing April 23, 1958.

F. W. GUTZWILLER is with the General Electric Company, Clyde, N. Y.

fuse manufacturers make maximum clearing I^2t data available on all types of low-voltage current-limiting fuses, approximations of this value are necessary. Of three fuse manufacturers consulted, all agreed that arcing I^2t should not exceed twice the melting I^2t for properly designed and functioning fuses. Since clearing I^2t is the sum of melting and arcing I^2t, maximum clearing I^2t may be conservatively approximated by multiplying the maximum melting I^2t by three.

Specific melting I^2t ratings as such are not published for most commercial low-voltage current-limiting fuses. Another approximation is therefore necessary until adequate fuse data are made available by manufacturers for this purpose. By referring to the melting-time–current characteristics of a particular fuse, the melting I^2t may be approximated by squaring the melting-current amperes at 0.01 second and multiplying by 0.01 second. This yields a value of ampere^2-seconds. The manufacturer's maximum tolerance in current or time should be introduced into this calculation to produce a more realistic maximum value. For example, Fig. 2 illustrates the melting-time–current characteristics of a typical line of current-limiting fuses of a type developed especially for semiconductor rectifier protection. The maximum rms melting current for the 15-ampere fuse at 0.01 second is 46 amperes plus 5% tolerance, or 48.3 amperes. The maximum melting I^2t approximation is $(48.3)^2 \times 0.01$ second, or 23.3 ampere^2-seconds. The approximation for maximum clearing I^2t of the fuse is 3×23.3 or 69.9 ampere^2-seconds. Actual tests on this particular fuse and similar types of fuses indicate that this method of approximation is very conservative.

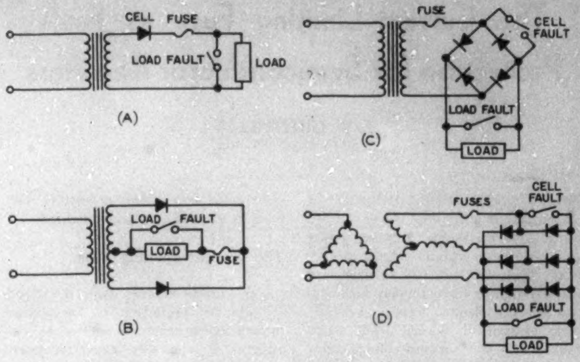

Fig. 3. Some simple current-limiting fuse protection circuits

A—Half wave
B—Full-wave centertap
C—Single-phase double-way or bridge
D—Three-phase double-way or bridge

In its simplest form, protection is provided as shown in Fig. 3(A), a fuse in series with a semiconductor rectifier. Protection of the rectifier will occur for any subcycle waveshape and magnitude of current within the interrupting rating of the current-limiting fuse if the maximum clearing I^2t of the fuse is equal to or less than the minimum I^2t rating of the rectifier cell. Usually the I^2t rating will be specified by the cell manufacturer as a value imposed with the cell already operating at maximum rated junction temperature and peak inverse voltage. Higher I^2t ratings may be available for such circumstances as a lower operating junction temperature preceding the surge (particularly applicable to germanium devices) and conditions where inverse voltage does not follow the fault current, for example, when a fuse interrupts the voltage supply.

The basic protection circuit shown in Fig. 3(A) and the co-ordination principle just described applies to any rectifier circuit in which current-limiting action is desired, and in which the fault current flows in one rectifier cell path at a time. Thus, fuses in the circuits of Fig. 3(B), (C), and (D) should also be selected to have a maximum clearing I^2t lower than the I^2t rating of any single rectifier cell in the circuit.

Line fusing as shown in Fig. 3(A), (C), and (D) protects the rectifier cells against severe d-c short circuits and also protects the remaining good cells against faults that result from a defective cell. The continuous rating of the fuse in any circuit should be adequate for handling maximum rated load indefinitely without blowing. Also, its interrupting rating must be greater than the available fault current in the circuit. Again, it should be emphasized that current-limiting fuses will usually provide positive protection only against severe faults. Other types of protective devices in the form of circuit breakers or conventional fuses should be provided for lower current overloads which the rectifier cells are capable of sustaining for more than a few cycles.

When N rectifier cells are connected in parallel with one another but in series with a single fuse, as shown in Fig. 4, the clearing I^2t of the fuse should be no greater than N^2 times the I^2t rating of the individual rectifier cells, if all the parallel cells share current equally. If the rectifier cells are derated for parallel operation to compensate for inequalities in current sharing, the relationship between the maximum clearing I^2t of the fuse and the I^2t rating of the individual rectifier cell may be expressed as follows (see the Appendix).

$$I^2t_f \le I^2t_c[N(1-S)+S]^2 \qquad (1)$$

where

I^2t_f = maximum clearing I^2t of fuse
$I^2t_c = I^2t$ rating of single rectifier cell
N = number of parallel rectifier cells
S = derating factor for parallel cell operation

When a current-limiting fuse in the primary of a transformer must be co-ordinated with a rectifier in the secondary,

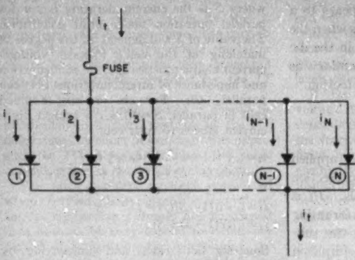

Fig. 4. Co-ordination of single fuse with parallel rectifier cells

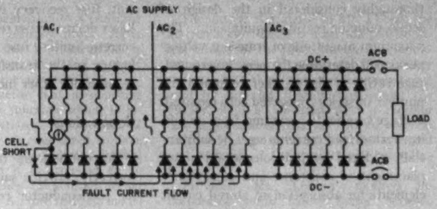

Fig. 5. Three-phase bridge rectifier providing noninterrupted service upon cell failure

their respective I^2t may be compared by the following equation, which is based on the premise that currents vary inversely as the voltage ratio of the windings:

$$I^2t_f \leq \left[\frac{V_s}{V_p}\right]^2 \times I^2t_c \qquad (2)$$

where

V_s = rated secondary voltage of transformer
V_p = rated primary voltage of transformer

Care must be taken in applying current-limiting fuses in the primary circuits of transformers to avoid having the inrush magnetizing current blow the fuse. In transformers operating close to saturation flux densities, inrush magnetizing currents may run as high as ten times full-load current.

Fuse Co-ordination for Isolation of Defective Rectifier Cells

For high-current semiconductor rectifier installations in which many cells are connected in parallel in each leg of the circuit, and where continuity of operation is essential, current-limiting fuses are used to isolate short-circuited cells from the circuit. With a defective cell isolated in less than a cycle, the rectifier equipment can continue to supply d-c power and, provided adequate load-carrying capacity remains in the leg, the defective cell, or cells, and fuse may be replaced at the convenience of the operator. A simple 3-phase bridge circuit of this type is shown in Fig. 5.

This circuit consists of six parallel matched cells in each leg of a bridge. A current-limiting fuse is connected in series with each cell. The fuses must have similar resistances in order not to unbalance the current sharing of the parallel rectifier paths. In the event that a rectifier cell short-circuits, a direct short circuit develops between the a-c lines for a part of each cycle. For example, if the indicated cell in phase 1 short-circuits, a fault current will flow as indicated whenever line AC_1 is positive with respect to line AC_3. To isolate the defective cell satisfactorily, fuse 1 must clear the fault current before any of the rectifier cells in phase 2 fail and before any of the fuses in phase 2 reach the melting point. Equation 1 may be used to co-ordinate fuse 1 with the rectifier cells, this being the case of a fuse in series with a group of parallel cells. To meet the fuse selectivity requirement that only the fuse adjacent to the faulty cell blow, equation 1 may be used by substituting the maximum melting I^2t value of the fuses for I^2t_c in the equation. Taking into account inequalities in parallel cell current sharing, and the ratio of clearing I^2t to melting I^2t for typical types of fuses, leads to the general conclusion that no less than three cells should be operated in parallel in a leg of this type of circuit if positive fuse selectivity is to be realized.

In the circuit of Fig. 5, the five parallel cells and fuses remaining in phase 1 after the faulty cell has been isolated should be capable of carrying rated current until replacement of the defective cell has been made.

Where d-c bus faults or overloads may be expected, a circuit breaker should be located in the d-c output of the rectifier to disconnect the fault before rectifier cell failure or fuse melting can occur. Tripping of a-c breakers may also be arranged to perform this function. Low-voltage current-limiting fuses are currently available for d-c bus interruption duty in ratings up to 1,200 amperes at 250 volts. A protective co-ordination chart of the type that has been described in the literature[4] is a useful tool in determining that the d-c fault protection functions before either rectifier cells or isolating fuses reach their respective maximum ratings under any d-c fault condition from a bolted bus fault, if this is a possibility, to mild overloads. An example of such a d-c fault co-ordination chart for a 400-ampere rectifier supply is shown in Fig. 6. For all current levels up to the maximum possible d-c bus fault, the circuit-breaker characteristic lies to the left of both the rectifier cell and fuse characteristics indicating satisfactory co-ordination for d-c faults.

Transient Voltage Considerations

The rectifying characteristics of germanium and silicon cells can be destroyed by voltage in excess of the transient peak inverse voltage rating, even if this excessive voltage is impressed across the cell for a small fraction of a cycle. For this reason, transient voltages must be

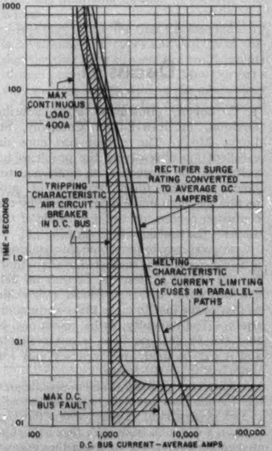

Fig. 6. Fault co-ordination chart for 400-ampere rectifier equipment of type shown in Fig. 5

thoroughly considered in the design of semiconductor rectifier equipment. The maximum magnitude of transient voltage peaks will determine the peak inverse voltage rating of the rectifier cells and the number of series-connected cells required. Voltage transients occurring from switching normal load currents may be substantially reduced by judicious selection and placement of resistance and capacitance elements for absorption of stored circuit energy. However, these techniques have little effect in dampening the transient voltages induced when a fault current with its extremely high associated energy is suddenly interrupted. To minimize induced voltages from fault currents, protective devices should not be over-abrupt in their interrupting action on fault current. In the case of the current-limiting fuse action described in Fig. 1, the maximum indicated slope $(-di/dt)$ of the current during arcing is an indication of the recovery voltage developed across the fuse. The magnitude of fuse recovery voltage is thus a function of fuse design and the parameters of the circuit in which the fuse is used.

In the parallel cell scheme of Fig. 5, the fuse recovery voltage is impressed directly across the cells in parallel with the fuse. In this type of application, the need for the right combination of fuse characteristics is obvious: the fuse should offer an optimum compromise of low clearing I^2t and low recovery voltage.

Depending on the specific rectifier circuit, fuse recovery voltage appears to a lesser degree across rectifier cells when the current-limiting fuse is located in the d-c bus or in the transformer secondary as required for other modes of protection.

Conclusions

Current-limiting fuses, when applied correctly, provide satisfactory protection for semiconductor rectifier cells. I^2t is proposed as a satisfactory means for rating semiconductor rectifier cells in the subcycle region. Satisfactory and simplified co-ordination between cells and fuses may be achieved by properly relating cell I^2t rating to maximum fuse clearing I^2t. This eliminates the necessity for complex fault current calculations in the subcycle region.

Appendix. Co-ordination of Current-Limiting Fuses with Parallel Rectifier Cells

Co-ordination between parallel cells and a current-limiting fuse is most critical when one rectifier cell (cell 1 in Fig. 4) is carrying maximum rated fault current, and all other parallel cells have maximum parallel mismatch, and are therefore carrying a minimum share of the total fault current i_t. In this figure there are N parallel rectifier paths, and each of the parallel paths other than cell 1 is assumed to be carrying a minimum current equal to

$$i_2=i_3=i_{N-1}=i_N=i_1(1-S)$$

where S is the current derating factor for parallel operation under fault conditions. The value of S will depend on the degree of matching of the cell's forward voltage-current characteristics and the configuration and impedance of interconnections between parallel cells. For six or less matched cells in parallel, $S=0.1$ for a typical high-current silicon rectifier cell.

$$i_t=i_1+i_2+i_3+\ldots+i_{N-1}+i_N$$
$$i_t=i_1+i_1(1-S)+i_1(1-S)+\ldots i_1(1-S)+i_1(1-S)$$
$$i_t=i_1+i_1(1-S)(N-1)$$
$$i_t=i_1[N(1-S)+S]$$

Squaring both sides, and multiplying by time t yields

$$i_t^2t=i_1^2[N(1-S)+S]^2t$$

By defining all currents as rms values and substituting the I^2t ratings of the fuse and the rectifier cells

$$I^2t_f=I^2t_c[N(1-S)+S]^2 \qquad (1)$$

Discussion

J. C. Lebens (Bussmann Manufacturing Division, McGraw-Edison Company, St. Louis, Mo.): The author has done an excellent job of resolving the problems involved in the protection of semiconductor junctions. The tough problem of protection has been made more difficult by the confusion concerning the magnitude of the amperes the fuse must interrupt.

One good way to overcome this confusion is by the use of I^2t as suggested by the author. He can obtain by test the I^2t that the cell can withstand and then equate this value to that of the fuse to make his co-ordination study. The difficulty, as he points out, is that the I^2t data on fuses is not available and it can be used with accuracy only for times less than 0.01 second.

In our study of the problem we did not use I^2t but converted the data on the cell to rms symmetrical amperes which put the data on a common basis with that available on commercial fuses. By using the concept of prospective current and virtual time the co-ordination between the safe time of the cell and the total clearing time of the fuse at all values of load may be established.

When a full wave rectifier fails, the current which the undamaged cell and its fuse sees is a pulse which may have different shapes depending on the characteristics of the circuit. Actually our tests indicate that representative data can be obtained by testing a single cell in series with the fuse on a low-voltage a-c circuit.

These tests showed that the damage data on the cell are conservative, once they are properly defined in rms symmetrical amperes. Because of this we are able to produce a current-limiting fuse of simplified construction which matches the damage characteristic of the cell. This substantially reduces the cost of the protection.

Originally we also were quite concerned with the effect of preloading on the capacity of the cell. Actually, preloading does not shift the damage characteristic appreciably.

Fundamentally, for complete protection, the thermal capacity of the fuse should be the same as that of the cell and it should be subjected to the same cooling. Practically this is virtually impossible so that tests were run to determine the effect of preloading and cooling on the cell damage characteristic. We were pleased to find that the effect did not make the co-ordination of the cell and the current-limiting fuse of simplified design impossible. The author has been instrumental in developing and in bringing into proper perspective the complete and accurate data so necessary to the solution of this problem.

Joint Discussion of Paper Nos. 58-927 and 58-928

I. K. Dortort (I-T-E Circuit Breaker Company, Philadelphia, Pa.): This paper and the paper by Gentry[1] attempt to lay the ground work for the selection of current-limiting fuses for the protection of semiconductor rectifiers on the basis of the I^2T capability of the individual cells. Since the forward resistance of semiconductors is far from linear, the use of I^2T as a criterion must be questioned. If the semiconductor had a constant voltage drop independent of current, its capability would be a function of IT. In actual fact the heat generated will fall somewhat between these two limits.

There is danger in the use of I^2T determined by short pulses of high current, when applied to circuits or conditions in which the peak fault current is limited to a considerably lower value. Normally this is considered safe because some heat may be assumed to flow into the sink in the latter case. However, the total heat generated can be considerably increased by the IT component.

If an IT component exists, it should be manifested in a sharp decrease of the I^2T determined by short pulses, as in this paper, and the I^2T determined from the surge current curves in the 1-to-3 cycle region.

The same problem must be considered when expressing fault currents in rms values. In this connection I should like to suggest that authors be very careful to define the period of integration for determining the rms value, especially when the periods are longer than $^1/_2$ cycle and shorter than 2 or 3 cycles. This applies to both cell and fuse manufacturers.

Figs. 5 and 6 refer to a 3-phase rectifier for a 400-ampere output using six parallel cells in each arm of the 3-phase bridge. The average loading per cell is approximately 22 amperes. Since cells of much higher current rating are available, I assume that the number of cells in parallel was chosen to permit several failures without interruption of service. Is this set-up considered typical for normal application or was it chosen only to illustrate the principles of protective co-ordination?

The author mentions that current-limiting fuses for d-c bus interruption duty are available in ratings up to 1,200 amperes at 250 volts d-c. It may please him to learn that 5,000-ampere fuses are standard catalog items today. They are not of the same type as the fuses used for individual cell protection, but are particularly adaptable for co-ordinated d-c protection.

Reference

1. See pages 746–50 of this issue.

F. E. Gentry: I agree with Mr. Dortort that the forward characteristic of a semiconductor rectifier is not linear. For instance, silicon rectifiers have a current-versus-voltage characteristic which is exponential in nature. However, when the voltage drop across the cell exceeds about 0.8 volt the voltage drop can be represented to a very good approximation by a constant voltage drop plus a resistive drop. As is shown in Fig. 3, this representation is adequate for the surge times and current levels considered in the analysis.

If the semiconductor had a constant voltage drop at the junction which is independent of current, and if the bulk of the semiconductor were considered to have finite heat capacity and infinite thermal conductivity, and if it is attached to an insulating surface, then the solution would be a function of It. A more realistic model would include thermal conductivity. For this particular set of conditions an analysis has been made by Diebold (see reference 4 of my paper) where in his equation 20 it is shown that temperature is a function of heat input and $\sqrt{t}$. With a constant voltage drop across the junction and a square wave input of current, the heat generated would be IV, with the result that the temperature at the junction would be a function of $\sqrt{I^2t}$.

As pointed out in my paper, the surge capability of a rectifier will deviate from the I^2t constant relationship for times longer than l^2/α. This is expected since the geometry chosen for this analysis is not adequate. In a previous and much better analysis[1] the deviation from the constant I^2t relationship is predicted for times up to 10 milliseconds. As for the direction of the deviation, the constant I^2t rating will result in a conservative rating for times longer than the time from which the rating was determined, since the constant I^2t curve is somewhat steeper than the actual failure curve. This is evident from Fig. 5.

1. Surge Current Failure in Semiconductor Rectifiers, F. E. Gentry. *MEE Thesis*, Syracuse University, Syracuse, N. Y., June 1957.

F. W. Gutzwiller: The extensive oral discussion and the two formal discussions submitted on this paper and the paper by Mr. Gentry indicate the significant interest which exists on the subject of semiconductor rectifier protection. It is the author's hope that this vital matter will be the subject of additional papers and discussion.

The author is grateful to Mr. Lebens for his remarks. There is a certain philosophical humor in the fact that the fuse manufacturer has seen fit to convert the rectifier cell data into the terms and language being used by him for fuse purposes, and the author, who is affiliated with a rectifier cell manufacturer, has seen fit to convert the fuse data into terms more easily developed and understood by rectifier cell manufacturers.

Provided Mr. Lebens' method incorporates ample safety factor between fuse clearing and cell failure points, it appears that the two methods are compatible.

Comments on the first part of Mr. Dortort's discussion are made by Mr. Gentry in his companion paper. The following comments apply to the latter part of Mr. Dortort's discussion.

For noninterrupted service when a rectifier cell fails, the rectifier supply shown in Figs. 5 and 6 requires a minimum of four cells in parallel in each leg of the circuit. Three of the four cells are necessary to provide adequate fuse selectivity during a cell fault, as pointed out in the section of the paper "Fuse Co-ordination for Isolation of Defective Rectifier Cells." A minimum of one additional parallel cell in each leg is necessary as a "spare" element to permit satisfactory operation and fuse selectivity if one cell has already failed. In this particular example, two additional parallel cells in each leg were necessary to provide sufficient short-circuit capacity for the maximum d-c bus fault of 4,000 amperes. These two cells also provide ample safety margin between the characteristic of the breaker and the characteristics of the fuses and cells at lower level overloads. Mr. Dortort is correct in stating that a rectifier cell of slightly larger current rating may have reduced the number of parallel cells required in each leg. In any event, however, the minimum number of parallel cells is four.

It is very gratifying that the fuse industry is developing new types and ratings of current-limiting fuses to meet the requirements of semiconductor rectifiers. Mr. Dortort's very welcome notification of the availability of 5,000-ampere fuses for d-c protection is further evidence of this activity.

Spinning Disk Random Selectors

G. A. ROBERTS
ASSOCIATE MEMBER AIEE

THIS PAPER describes two spinning disk random selectors that generate equally-likely independent random numbers. One selector is a small, portable, single-decade unit, and the other is a 3-decade unit with the modulus adjustable from 10 to 1,000 in increments of 10.

Random numbers are used in numerous applications, some of which are, for example: selection of signals or input information for psychophysical experiments, simulation and testing of complex physical systems, setting of safe combinations, performance of Monte Carlo experiments, and all applications where random samples are needed. The random selectors described in this report are useful in all applications where a large quantity of independent random numbers are required or where random numbers other than those available in standard tables are desired.

Theory of Operation

The spinning disk random selector may be separated into two functional parts: an equally-likely number generator, and a random source, shown in the block diagram of Fig. 1. The equally-likely number generator consists of a recurrent pulse generator, an electronic counter of

the proper modulus, and a number readout unit.

Assume the counter to have a modulus of N (i.e., N unique, stable states), and the period between pulses to be t. One modulus cycle then has a period T of Nt. The counter must pass through each of its N states for every modulus cycle. Because the input pulses are equally spaced, the counter will, on the average, be in each of its N states for the same period of time. If the counter is recurrently stopped in such a way that the stopping time is uniformly distributed over the modulus cycle, then the probability of a number being selected is equal to the faction of time the counter stays on that number.

If the selection time is random and the probability density of the selection time is uniformly distributed over T (the modulus period), then the numbers selected will be random and equally likely. If successive selection times are independent then successive numbers will be independent, with no patterning. A simplified block diagram of the equally-likely independent number generator is shown in Fig. 2.

The mechanism for randomizing the number selection must operate the selection switch at a random time and provide a uniform probability density function over the modulus cycle T. Assume that a device is available that delays an input pulse a random period of time. Further asume that the probability density function for this delay is approximated by a normal distribution. A sketch of this typical delay function is shown in Fig. 3.

The probability density function of Fig. 3 does not begin to approximate a uniform function. But this function is in the infinite time domain, whereas the desired function, the probability density function over the modulus period T, is over a finite time domain T. By taking the distribution of Fig. 3 and wrapping it around a cylinder of circumference T, and summing the ordinates, the probability density function for the interval T is obtained.* The larger the ratio of σ to T, the better is the approximation of the wrap-around probability density to a

uniform distribution. In Fig. 4 is shown a curve for the peak-to-peak difference of the probability density function over T as a function of the ratio of the standard deviation σ of the delay distribution curves to the modulus period T.

The random selectors described in this report are manually operated in the selection process. Therefore it is necessary to know if the foregoing assumptions are met when the randomizing device is a human operator. Two experiments have been conducted. The purpose of the first was to determine the smallest value of σ. A subject was given a stop watch and told to stop the watch as close to 4 seconds as possible. Several hundred trials were made with a result for a smaller σ of 35 milliseconds for the best of five subjects. In this experiment the subject has the best possible timing information available. A second experiment was run where the subject had no external timing information. This experiment utilized an electronic counter for time interval measurement. The subject was told to start the counter, count "one one-thousandth, two one-thousandths" and then stop the counter. The subject was to try to be as consistent in the formation of this time interval as possible. A value of 185 milliseconds was measured for σ. The results of this experiment are shown in Fig. 5 and, for comparison, a normal curve with the same mean and σ is plotted.

In summary, equally-likely random numbers are generated as follows: An electronic counter of modulus N is driven continuously by a recurrent pulse generator. Therefore, on the average, the counter is in each of its N possible states the same length of time and each number is equally likely. A selection switch is placed between pulse generator and counter so that the counter can be stopped when a selection is desired. Randomness is obtained by operating the counter at a relatively high rate with respect to the period between operations of the selection switch. Anything that operates the selection switch, or a human operator, will have some variance in the timing; if this variance is large with respect to the period for one cycle of modulus N, then independence of number selections is obtained.

Circuit Design

The two random selectors described are both designed for manual operation. The spinning disk random selector, type *C*, model 1, is a 3 decade, adjustable-modulus, semiportable unit. Fig. 6 shows a detailed block diagram of this unit which, as described here, was designed to meet the following requirements:

1. The selection process should be manual and occur no faster than once per second.
2. The maximum modulus of the counter should be 1,000 and should be adjustable from 10 to 1,000 in increments of 10.
3. The counter should use cold-cathode counter tubes because of their low cost, small size, low power requirements, and direct read-out.
4. In addition to the modulus N selection, an equally-likely binary output should be provided.

The use of cold-cathode counter tubes sets an upper limit to the operating speed of the counter. The type *GC-10-D* tube, which is a decade counter, has a maximum counting rate of 20 kc, and thus has an output of 2 kc. The *GC-10-D* does not have separate pin connections for each cathode; therefore it cannot be used as a preset counter. The *GS-10-C* has separate cathodes but is limited in counting speed to 4 kc. Therefore, the maximum counting speed can be achieved by using one *GC-10-D* and two *GS-10-C* tubes. This arrangement will also allow the desired modulus adjustment. (One-hundred-kc-per-second cold-cathode tubes are now available.)

For this particular counter, which has a maximum modulus of 1,000, the maximum modulus period is 0.02 second. If a criterion is selected of 1% flatness in the sequence 1% flatness in wrap-around probability density, then the smallest σ allowable is 0.03 second; see Fig. 4. Any σ larger than 0.03 second will result in a more uniform wrap-around probability density. The experimentally measured standard deviations of 0.035-second minimum, and 0.185 nominal, indicate that

the manual operation will certainly meet this criterion.

If a "safety factor" is desired, the operator of the equipment should not watch the counter tubes prior to actuating the selection switch, since timing information may be obtained from the hundreds counter. The result of receiving this information may be a reduction in σ, although undoubtedly it will still be above the minimum allowable of 30 milliseconds.

The modulus of the counter is set by two switches. The switches select one cathode on the tens counter and one on the hundreds counter. The outputs from the switches are applied to a coincidence circuit in such a way that when a voltage exists between both the selected cathodes and ground, the counter is forced to reset. Thus, any modulus between 10 and 1,000 in increments of 10 may be obtained.

The output of the binary unit is applied to the modulus N counter. A *GS-10-D* counter is used for the units decade. (This tube may be obtained from the Atomic Instrument Company of Cambridge, Mass.) All cathodes except the output cathode are tied together in this tube; therefore, only decade counting can be obtained. The output indicator is an integral part of the counter, and it utilizes a gaseous discharge glow that can appear in one of ten different positions on a circular path. The angular position indicates the count. The output cathode and resistor produce one output pulse for every ten input pulses to the counter. This pulse is coupled to the input of the next counter. The physical orientation of the tube relative to the bezel should be such that the output cathode lines up with the O on the bezel.

The tens and hundreds counters are identical to each other and are similar to the units counter. The primary difference is that the tens and hundreds counters have the lower counting speed of 4 kc, and all cathodes are brought out separately. A cathode is illuminated by a current flowing through it, and a voltage drop is developed across the cathode resistor. Since all cathodes are brought out separately, and each has a separate resistor, the location of the cathode glow can be identified by the presence of a voltage. This provides a convenient method for identifying the state of the counter. In this particular application an 11-position switch is used with the tens and hundreds counters to select the cathodes that trigger the automatic reset circuit. As mentioned, when coincidence of these two switch outputs occurs, the tens and hundreds counters are reset to "000." The coincidence circuit drives a reset circuit in order to provide a sufficiently long reset pulse. The reset circuit is a multivibrator followed by a reset amplifier for the tens counter and one for the hundreds counter. Since the reset circuit insures that resetting goes to completion, there is no bias towards the last number in the modulus, or "000."

The spinning disk random selector, type *C*, model 3, was designed as a lightweight, handy unit and is used for small applications such as setting safe combinations or where a few selections are needed for a particular problem. The input frequency to the counter is approximately 500 cycles per second; this results in a modulus period of approximately 20 milliseconds. Therefore, better than 1% peak-to-peak flatness will be achieved in the wrap-around probability density function.

This unit was designed around two 240-volt photoflash batteries in series. The counter and read-out tube is *GC-10-A* type *5823* tube is used as a cold-cathode relaxation oscillator.

Equipment and Circuits

The electronic spinning disk random selector (type *C*, model 1) is shown in Fig. 6(A). The complete circuit diagram is shown in Fig. 7. Complete lists of components, together with construction details, are contained in reference 1.

The 460- and 420-volt busses are nominal values. The exact settings of these voltages will depend on the average d-c line voltage and particular counter tubes in the equipment. The equipment may be expected to operate with 30% variation in the line voltage with new tubes. Fig. 8 shows the electronic spinning disk random selector (type *C*, model 3) and a complete circuit diagram.

Some of the Fundamental Aspects of Ground Resistance Measurements

E. B. CURDTS
MEMBER AIEE

THE PRACTICAL measurement of the resistance to earth of a very small symmetrical electrode is a fairly simple procedure and does not call for a great deal of knowledge of the fundamentals involved. However, as such electrodes increase in size and become more complex in their shape, there is greater need for a better understanding of the basic principles.

It is the purpose of this paper to present some of these basic principles in their simplified form to assist in making realistic measurements. To accomplish this objective a homogeneous single-layer earth will be assumed throughout this discussion. These simplifications will not affect the basic principles involved, but on the other hand there can be no theoretical substitute for actual field measurements. However, a better understanding of the problem should greatly assist in anticipating the measurement procedures.

Statement of the Measurement Problem

When a resistance measurement is to be made on a ground grid of a certain size and shape, the following questions immediately arise:

1. At what distance from the ground under test should the current reference electrode be placed?
2. Where should the potential reference electrode be placed in relation to the current reference electrode and the ground under test?
3. What effect does the size and shape of the ground under test have on the answers to questions 1 and 2?

Basic Analysis

The network is shown schematically in Fig. 1. As a first analytical step in obtaining a theoretical answer to these three questions the mutual resistance to true earth can be calculated for a sink (point 1) and a current source (point 3) spaced at a remote or infinite distance from point 1, as given by

$$Q(S_{12})=\frac{\rho}{2\pi}\frac{1}{S_{12}} \qquad (1)$$

where S_{12} is the spacing between point 1 and a movable point 2. This mutual resistance is shown plotted in Fig. 2 for $\rho/2\pi=1{,}000$, ρ being the resistivity of the earth. It approaches infinity near point 1 and approaches zero near the remote current source 3.

In Fig. 3 hemispherical metal electrodes with radii r_1 and r_2 are shown around point 1, together with the same mutual resistance curve as given in Fig. 2. The resistance to true earth is then determined by a point on this curve representing, in terms of S_{12}, the radius of the hemisphere chosen. Hemisphere radius $r_1=200$ feet results in a total resistance of 5 ohms from its edge to true earth, and $r_2=500$ feet results in a total resistance of 2 ohms.

The mathematical expression for the relationship of the hemisphere under test and its incremental resistance at any distance S_{12} is then given by

$$R_{(1-3)(1-2)}=\frac{\rho}{2\pi}\left(\frac{1}{S_r}-\frac{1}{S_{12}}\right) \quad S_{12}\overline{>}S_r \qquad (2)$$

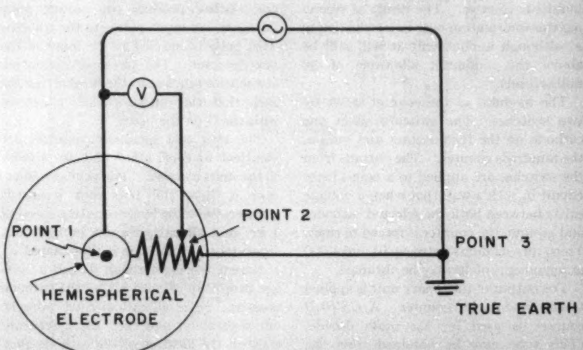

Fig. 1. Schematic network for measurement of resistance to true earth of hemispherical electrode

---

Paper 58-106, recommended by the AIEE Special Instruments and Auxiliary Apparatus Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted November 6, 1957; made available for printing May 20, 1958.

E. B. Curdts is with the James G. Biddle Company, Philadelphia, Pa.

This relationship is shown in Fig. 3 by heavy curves for electrode radii r_1 and r_2. These curves start at the edges of the hemispheres with values of $R_{(1-3)(1-2)}=0$, and approach the total resistance values of 2 and 5 ohms for r_1 and r_2 respectively. They reach the full value of resistance to true earth at $S_{12}=\infty$. At $S_{12}=1{,}500$ feet the incremental resistance of the larger electrode is a smaller percentage of its total resistance than the smaller hemisphere. In other words, the larger the ground under test, the greater the distance must be between it and reference point 2. For example, for $r_1=200$ feet and a test accuracy of 90%,

$$R_{(1-3)(1-2)}=\frac{1{,}000}{200}\times 0.90=4.5$$

$$=\frac{1{,}000}{200}-\frac{1{,}000}{S_{12}}$$

$$S_{12}=\frac{1{,}000}{0.5}=2{,}000 \text{ feet}$$

For $r_2=500$ feet and the same accuracy

$$R_{(1-3)(1-2)}=\frac{1{,}000}{500}\times 0.90=1.8$$

$$=\frac{1{,}000}{500}-\frac{1{,}000}{S_{12}}$$

$$S_{12}=\frac{1{,}000}{0.2}=5{,}000 \text{ feet}$$

Stated differently, the percentage of the total resistance obtained for any distance S_{12} is given by

$$\% R_\infty=\frac{\frac{\rho}{2\pi}\left(\frac{1}{S_r}-\frac{1}{S_{12}}\right)}{\rho/2\pi\ 1/S_r}100$$

$$=\left(1-\frac{S_r}{S_{12}}\right)100 \tag{3}$$

Inspection of equation 3 shows that any error resulting from any one location of point 2 is a function of S_r only, and is not affected by earth resistivity.

Summation of Mutual Resistances

It is to be emphasized that the foregoing analysis is based on the current source 3 being spaced an infinite distance from the ground under test. Considering the problem for the case where source 3 is located at a more practical distance from point 1, the mutual resistances $Q(S_{13})$ and $Q(S_{23})$ have a definite influence on the measurement, the complete expression being given by

$$R_{(1-3)(1-2)}=\frac{\rho}{2\pi}\left(\frac{1}{S_r}-\frac{1}{S_{12}}-\frac{1}{S_{13}-S_r}+\frac{1}{S_{23}}\right) \tag{4}$$

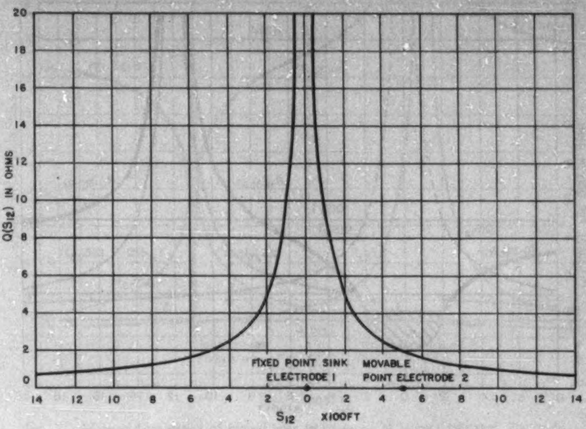

Fig. 2. Mutual resistance to true earth of point electrode

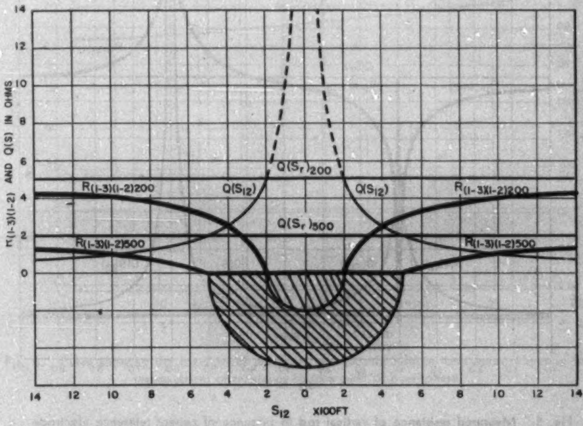

Fig. 3. Mutual resistance to true earth of hemispheres having radii of 200 and 500 feet

The mutual resistance between points 1 and 3 is a single value for a fixed location of point 3, and is given by

$$Q(S_{13})=\frac{\rho}{2\pi}\ \frac{1}{S_{13}-S_r} \tag{5}$$

The mutual resistance between the movable point 2 and the fixed point 3 is a variable given by

$$Q(S_{23})=\frac{\rho}{2\pi}\ \frac{1}{S_{23}} \tag{6}$$

Fig. 4 shows an electrode at 1 with $r_1=200$ feet, and a current point electrode 3 at a distance of 1,200 feet from point 1. By equation 5

$$Q(S_{13})=1{,}000\left(\frac{1}{1{,}200-200}\right)=1.0 \text{ ohm}$$

Since by equation 4 this value is subtracted in determining $R_{(1-3)(1-2)}$, it is readily seen that the proximity of electrode 3 to point 1 can adversely affect

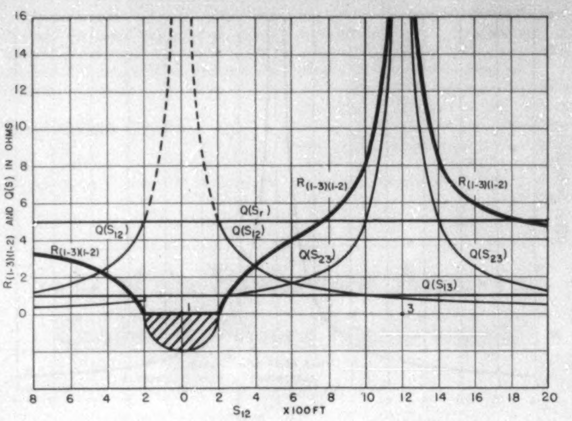

Fig. 4. Measured resistance of hemisphere in presence of current reference electrode

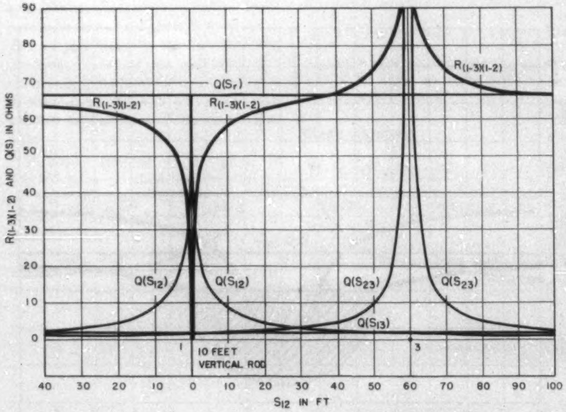

Fig. 5. Measured resistance of vertical rod in presence of current reference electrode

the measurement. The constant value of $Q(S_{13}) = 1.0$ ohms is shown in Fig. 4.

Fig. 4 also shows the variable mutual resistance $Q(S_{23})$ as calculated from equation 6, together with $Q(S_{12})$ from Fig. 2.

The heavy curves show the resistance values $R_{(1-3)(1-2)}$ as calculated from equation 4 and based on the potential reference point 2 being moved along a straight line from the far side of point 1 to the far side of point 3. A study of these curves reveals interesting information concerning the values of $R_{(1-3)(1-2)}$ for three of the many possible locations of point 2 in relation to the current source and sink. For example, if S_{12} is chosen as 50 and 150% of S_{13}, 600 and 1,800 feet from point 1 in Fig. 4, the following values are obtained:

Position of Electrode 2	No. of Feet From Point 1	Ohms
(A) On far side of point 1	600	2.88
(B) Between points 1 and 3	600	4.0
(C) On far side of point 3	1,800	5.11

In the case of position (A), $R_{(1-3)(1-2)}$ will be less than the resistance to true earth by at least $Q(S_{13}) = 1.0$ ohm even after increasing S_{13} to infinity. In the cases of positions (B) and (C), $R_{(1-3)(1-2)}$ can be made to equal the resistance to true earth at some value of S_{12}, to be determined.

Resistance to Earth Versus Measured Resistance

If in equation 4 $Q(S_{12})+Q(S_{13})$ can be made to equal $Q(S_{23})$, they will cancel and $R_{(1-3)(1-2)}$ will equal $Q(S_r)$, the true ground resistance. It can be shown mathematically that this is true, in the simplified case being analyzed here, for the (B) and (C) locations of electrode 2 as follows:

$$\left.\begin{array}{ll}\text{(B).}\ S_{12}=\dfrac{-1+\sqrt{5}}{2}S_{13}=0.62\,S_{13} & (7)\\ \text{(C).}\ S_{12}=\dfrac{1+\sqrt{5}}{2}S_{13}=1.62\,S_{13} & (8)\end{array}\right\} S_r \ll S_{13}$$

Equations 7 and 8 show that if the potential reference electrode is placed out from point 1 along the straight line through point 3 at either 62% or 162% of the spacing between points 1 and 3, then a resistance will be measured which is equal to the total resistance of the earth surrounding the ground under test. Such a simple mathematical relationship would apply precisely only in the case of point electrodes throughout. It also applies with negligible error to hemispherical or other shaped grounds if they are not too large in relation to S_{13}. For example, a single vertically driven rod or a buried wire (two commonly used electrode arrangements) will be similar to the hemisphere in this respect, their length influencing this relationship even less than the radius of the hemisphere.

Curves for a single vertically driven rod are shown in Fig. 5. It will be seen that the $Q(S_{13})$ curve crosses the $Q(S_{23})$ curve approximately midway between points 1 and 3. This means that in the case of a single driven rod, at least, the total resistance of the earth surrounding it should be found at approximately 62 and 162% of the straight-line distance through points 1 and 3 even for rod lengths which are appreciable in relation to S_{13}.

The case of a single straight buried wire, measured as shown in Fig. 6, is plotted in Fig. 7. It will be seen that the $Q(S_{12})$ curve also crosses the $Q(S_{23})$ curve approximately midway between points 1 and 3. As in the case of the vertical rod, this means that the total resistance of the earth surrounding a

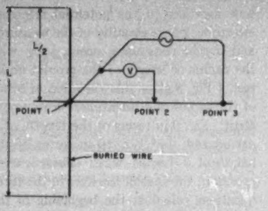

Fig. 6. Schematic network for measurement of resistance of buried wire in presence of current reference electrode

buried wire, when measured as shown in Fig. 6, should be found at approximately 62% and 162% of the straight-line distance through points 1 and 3 even for wire lengths which are appreciable in relation to S_{13}.

Various authors in writing on this subject have stated that the total resistance of the ground under test can be determined by placing point 2 on the opposite side from point 3. Figs. 4, 5, and 7 show that such measurements will always be less than the true resistance by the value of $Q(S_{13})$ and the difference between the values of $Q(S_{12})$ and $Q(S_{23})$.

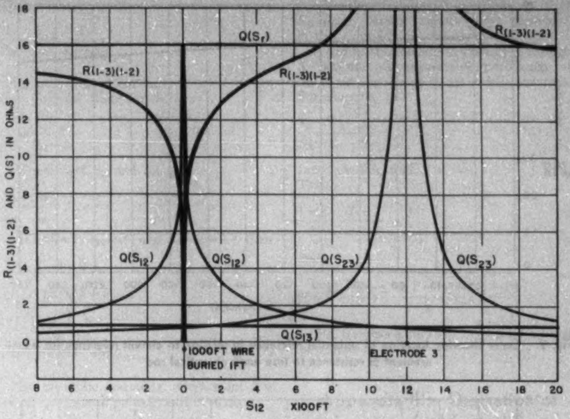

Fig. 7. Measured resistance of buried wire in presence of current reference electrode

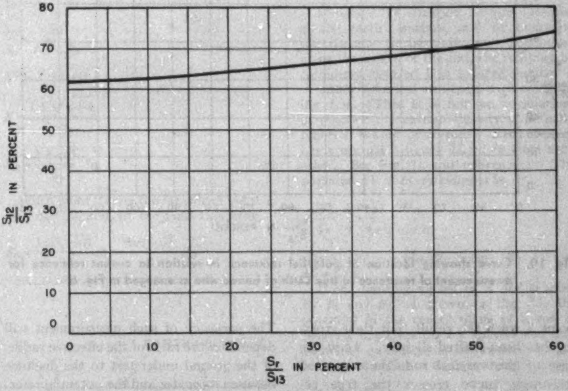

Fig. 8. Curve showing the location of potential reference in relation to current reference for measurement of resistance to true earth of hemisphere

Summary

Several examples of how ground resistance measurements are affected by the size and shape of the ground under test, and the location of the reference electrodes, are summarized as follows:

Fig. 2 shows the basic characteristic curve of the resistance to true earth at increasing distances from a point designated by electrode 1. It indicates that most of the resistance exists within a very small distance from the point. The curve, under conditions of constant current, also represents the voltage gradient for any radial increment of earth surrounding point 1, indicating much higher gradients nearer the ground under test.

Fig. 3 shows how an increase in ground grid radius decreases the total resistance to earth and the slope of the resistance-distance curve. The figure also reveals that ground electrodes of larger radii require a greater distance to reach their final resistance values.

Fig. 4 shows how the shape of the measured resistance curve is influenced by the various mutual resistances involved as the current reference electrode is brought from infinity to the vicinity of the ground under test, as shown in Fig. 1. It also indicates the results to be expected by placing the potential reference electrode at various locations along a straight line from the far side of ground electrode 1 to the far side of current reference electrode 3. At only two locations of potential reference electrode 2 along this line does the measured resistance represent the total resistance of ground electrode 1, at approximately 62% and 162% of the space between points 1 and 3.

Fig. 5 shows the results of replacing the hemispherically shaped electrode with a rod driven vertically into the earth. Here the mutual resistance of the rod as a function of distance is somewhat different from that of point 3, with the result that their crossing has been shifted slightly. This causes the measured resistance curve to cross the true resistance line at a distance somewhat different from that given for a hemispherical electrode.

Fig. 7 shows the results of replacing the hemispherically shaped electrode with a buried wire measured as shown in Fig. 6. Here the mutual resistance of the buried wire as a function of distance is also somewhat different from that of

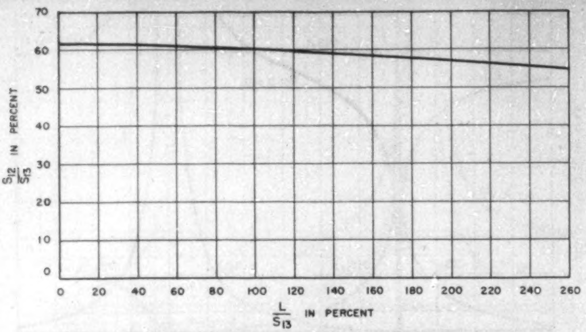

Fig. 9. Curve showing location of potential reference in relation to current reference for measurement of resistance to true earth of vertical rod

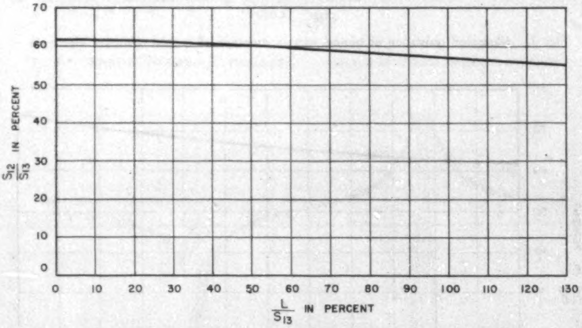

Fig. 10. Curve showing location of potential reference in relation to current reference for measurement of resistance to true earth of buried wire as arranged in Fig. 6

point 3, with the result that their crossing has been shifted slightly. As in the case of the vertical rod, the measured resistance curve crosses the true resistance line at a distance somewhat different from that given for a hemispherical electrode.

Practical Conclusions

The conclusions to be drawn from this analysis which theoretically answer the questions raised at the beginning of this paper are as follows:

If the current reference electrode is located at a distance so remote from the ground under test that its mutual resistances can be neglected, the measured resistance for any given size and shape of ground under test approaches the actual resistance to true earth as the distance of the potential reference electrode in relation to the ground under test is increased. The accuracy of such measurement will depend on the ratio of the effective radius of the ground under test to the distance between its center and the potential reference electrode.

Because so remote a location of the current reference electrode would ordinarily be impractical, the influence of its mutual resistances must be considered. Fortunately, these mutual resistances become additive in their effect on the measured resistance so that, at a point in the order of 60% of the distance between the effective center of the ground under test and the current reference electrode, the measured and actual resistances become equal. Although the theoretical analysis shows that the measurement can also be made on the far side of the current reference electrode, there would appear to be no practical justification for using a test connection of this extent.

Curves given in Figs. 8, 9, and 10 show how locations of the potential reference electrode, where equality of the measured and actual resistances occur, vary with the radius or length of the ground under test. Fig. 8 gives this variation in terms of the radius of a hemisphere or its equivalent; Fig. 9 in terms of the length of a driven rod, and Fig. 10 in terms of the length of a buried wire. These curves represent the specific answers to the three questions raised at the beginning of the paper, and provide the theoretical solution to the measurement problem.

Appendix I. Derivation of Equations 1, 2, and 4

The derivation of equation 1 for point electrodes 1 and 2 with point 3 at infinity follows: The radial current density at distance S from point 1 is given by

$$J=I/2\pi S^2$$

and the electric intensity at the distance S for an earth resistivity of ρ, will be

$$E(S)=I\rho/2\pi S^2$$

The potential at the distance S is then

$$\int_{S_{12}}^{\infty} E(S)dS=I\rho/2\pi S_{12}$$

and the mutual resistance of points 1 and 2 is

$$Q(S_{12})=\frac{\rho}{2\pi}\,\frac{1}{S_{12}} \tag{1}$$

The derivation of equation 2 for a hemispherical electrode surrounding point 1 follows: The voltage between points 1 and 2 due to the presence of a metallic hemispherical electrode at point 1 is

$$\int_0^{S_r} \rho_0 I/2\pi S^2 dS+\int_{S_r}^{S_{12}} \rho I/2\pi S^2 dS$$

where S_r is the radius of the hemisphere and ρ_0 is its resistivity. The measured resistance then becomes

$$R_{(1-3)(1-2)}=Q(S)_1=\int_{S_r}^{S_{12}} \rho/2\pi S^2 dS$$
$$=\frac{\rho}{2\pi}\left(\frac{1}{S_r}-\frac{1}{S_{12}}\right) \quad \rho_0\ll\rho \tag{2}$$

The derivation of equation 4 for a hemispherical ground and with point 3 moved toward point 1 follows: The presence of point 3 in the vicinity of point 1 introduces an additional voltage between points 1 and 2 which is given by

$$-\int_{S_{13}-S_r}^{S_{23}} \rho I/2\pi S^2\, dS-\int_{S_{13}}^{S_{13}-S_r} \rho_0 I/2\pi S^2 dS$$
$$=\int_{S_{23}}^{S_{13}-S_r} \rho I/2\pi S^2 dS$$
$$=\frac{\rho I}{2\pi}\left(\frac{1}{S_{23}}-\frac{1}{S_{13}-S_r}\right) \quad \rho_0\ll\rho$$

Therefore

$$Q(S)_3=\frac{\rho}{2\pi}\left(\frac{1}{S_{23}}-\frac{1}{S_{13}-S_r}\right) \text{ and}$$

$$R_{(1-3)(1-2)}=Q(S)_1+Q(S)_3$$

$$=\frac{\rho}{2\pi}\left(\frac{1}{S_r}-\frac{1}{S_{12}}-\frac{1}{S_{13}-S_r}+\frac{1}{S_{23}}\right) \qquad (4)$$

where $R_{(1-3)(1-2)}$ equals the measured resistance, the current passing through the earth between points 1 and 3, and the voltage measured between points 1 and 2.

Appendix II. Derivation of Equations 7 and 8

For $R_{(1-3)(1-2)}$ to equal $Q(S_r)$ the remaining mutual resistance terms in equation 4 must equal zero. Therefore

$$\frac{1}{S_{23}}=\frac{1}{S_{12}}+\frac{1}{S_{13}-S_r}$$

When point 2 is between points 1 and 3, and since points 1, 2, and 3 are in a straight line,

$$S_{12}=S_r+S_{r2}$$

$$S_{13}-S_r=S_{r2}+S_{23}$$

$$S_{13}=S_{12}+S_{23}$$

Therefore

$$\frac{1}{S_{23}}=\frac{1}{S_{12}}+\frac{1}{S_{r2}+S_{23}}$$

$$\frac{S_{23}}{S_{12}}=\frac{S_{r2}}{S_{r2}+S_{23}}=\frac{S_{12}-S_r}{S_{12}-S_r+S_{23}}$$

$$=\frac{S_{12}-S_r}{S_{13}-S_r}$$

Where $S_r \ll S_{13}$ and S_{12}:

$$\frac{S_{23}}{S_{12}}=\frac{S_{12}}{S_{13}}$$

Let $S_{13}=1$, $S_{12}=X$, and $S_{23}=1-X$; then

$$X^2+X-1=0$$

$$X=\frac{-1\pm\sqrt{1+4}}{2}$$

$$S_{12}=\frac{-1+\sqrt{5}}{2}\,S_{13} \qquad (7)$$

By the same reasoning, when point 2 is on the far side of point 3, and $S_r \ll S_{13}$

$$S_{12}=S_{13}+S_{23}$$

$$\frac{1}{S_{12}-S_{13}}=\frac{1}{S_{12}}+\frac{1}{S_{13}}$$

$$\frac{S_{12}}{S_{13}}=\frac{S_{13}}{S_{12}-S_{13}}$$

$$X^2-X-1=0$$

$$X=\frac{1\pm\sqrt{1+4}}{2}$$

$$S_{12}=\frac{1+\sqrt{5}}{2}\,S_{13} \qquad (8)$$

When point 2 is on the far side of point 1, $S_{23}=S_{12}+S_{13}$ and, by the same reasoning,

$$S_{12}=\frac{1\pm\sqrt{-3}}{2}\,S_{13}=\frac{1\pm j\sqrt{3}}{2}\,S_{13}$$

an imaginary quantity, indicating that $R_{(1-3)(1-2)}$ cannot equal $Q(S_r)$ anywhere in this direction on the earth's surface.

It can further be shown that even though S_r becomes an appreciable percentage of S_{13} equations 7 and 8 are fairly accurate. For example, in

$$\frac{S_{23}}{S_{12}}=\frac{S_{12}-S_r}{S_{13}-S_r}$$

Let $S_{12}=XS_{13}$ and $S_r=YS_{13}$.
Then

$$\frac{1-X}{X}=\frac{X-Y}{1-Y}$$

and

$$X=\frac{2Y-1+\sqrt{(2Y-1)^2+4(1-Y)}}{2}$$

Fig. 8 shows a curve of S_{12}/S_{13} for a range of values of S_r/S_{13}.

Appendix III. Derivation of Equation for Vertical Rod Electrode

To derive the equation for the potential at the earth's surface, and by assuming the current to be uniformly distributed along the length of the rod, the rod may be considered divided into a large number n of nearly spherical elements, each conducting I/n. (This is a fair approximation; in practice the current density is actually higher at the end of the rod.) Each element has a mutual distance $dL=L/n$ from each other. See Fig. 11 and reference 1. The potential dV of every element is

$$\rho\,\frac{I/n}{4\pi}\,\frac{1}{y}=\frac{\rho I}{4\pi L}\,\frac{d\alpha}{\sin\alpha}$$

where $\sin\alpha=y\,d\alpha/dL$ from Fig. 11 and $dL=L/n$.

If the limiting values of α are denoted by β_1 and β_2, as shown in Fig. 11, the potential in the center plane of a rod of length 2 L, containing 2 n spheres and thus including its image, is determined by the length and radius of the rod and given by

$$\frac{\rho I}{4\pi L}\int_{\beta_1}^{\pi-\beta_1}\frac{d\alpha}{\sin\alpha}=\frac{\rho I}{2\pi L}\ln\left(\cot\frac{\beta}{2}\right)$$

$$=\frac{\rho I}{2\pi L}\left(\ln\frac{2L}{a}\right)$$

where $L \gg a$

Thus the voltage between points 1 and 2 with a current reference at point 3 is

$$V=\frac{\rho I}{2\pi L}\left(\ln\frac{2L}{a}\right)-\frac{\rho I}{4\pi L}\int_{\beta_2}^{\pi-\beta_2}\frac{d\alpha}{\sin\alpha}+\frac{\rho I}{2\pi}\int_{S_{23}}^{S_{13}-a}\frac{dX}{X^2}$$

$$=\frac{\rho I}{2\pi L}\left(\ln\frac{2L}{a}-\ln\frac{\sqrt{L^2+S_{12}^2}+L}{S_{12}}\right)+\frac{\rho I}{2\pi}\left(\frac{1}{S_{23}}-\frac{1}{S_{13}-a}\right)$$

and

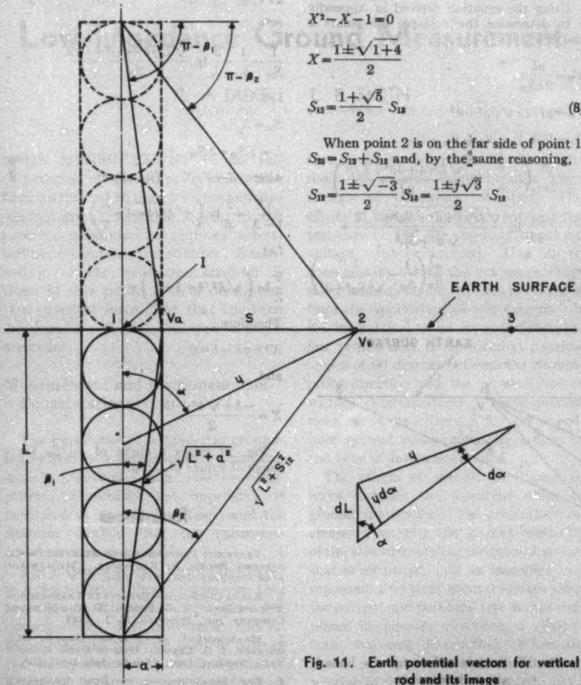

Fig. 11. Earth potential vectors for vertical rod and its image

$$R_{(1-3)(1-2)}=\frac{\rho}{2\pi}\left(\frac{1}{L}\ln\frac{2L}{a}-\right.$$

$$\left.\frac{1}{L}\ln\frac{\sqrt{L^2+S_{12}^2}+L}{S_{12}}+\frac{1}{S_{23}}-\frac{1}{S_{13}-a}\right)$$

To show that equations 7 and 8 are fairly accurate for various lengths of driven rods as well as for hemispheres, let

$$\frac{\rho}{2\pi}\left(\frac{1}{S_{23}}-\frac{1}{S_{13}-a}-\frac{1}{L}\ln\frac{\sqrt{L^2+S_{12}^2}+L}{S_{12}}\right)=0$$

or

$$\frac{1}{S_{23}}-\frac{1}{S_{13}}=\frac{1}{L}\ln\frac{\sqrt{L^2+S_{12}^2}+L}{S_{12}}$$

where $S_{13}\gg a$
Let

$$S_{12}=XS_{13}$$

$$L=YS_{13}=ZS_{12}$$

where $Z=Y/X$. Therefore

$$\frac{X^2}{1-X}=\frac{1}{Z}\ln(\sqrt{1+Z^2}+Z)$$

Let

$$\frac{1}{Z}\ln(\sqrt{1+Z^2}+Z)=b$$

Therefore

$$X^2+bX-b=0$$

and

$$X=\frac{-b+\sqrt{b^2+4b}}{2}$$

Fig. 9 shows a curve of S_{12}/S_{13} for a range of values of L/S_{13}.

Appendix IV. Derivation of Equation for Buried Horizontal Wire Electrode

Following the same method of solution of the problem as given in Appendixes I and III, and assuming the connection to the buried wire to be insulated, the geometry of the wire and its image is determined as shown in Fig. 12. Here the limiting values of the angles involved are determined by the length, depth, and radius of the wire, which determine the voltages involved, and the measured resistance at point 2 in the center plane or earth surface with a current reference at point 3.

Using the equation derived in Appendix III to determine the voltages of the wire, its image, and that of point 2

$$V_1=\frac{\rho I}{2\pi L}\ln\left(\cot\frac{\beta_1}{2}\right)$$

$$V_i=\frac{\rho I}{2\pi L}\ln\left(\cot\frac{\beta_i}{2}\right)$$

$$V_{12}=\frac{\rho I}{\pi L}\ln\left(\cot\frac{\beta_2}{2}\right)$$

Using the equation derived in Appendix I to determine the voltages for points 2 and 3

$$V_{23}=\frac{\rho I}{2\pi S_{23}}$$

$$V_{13}=\rho I/2\pi\sqrt{S_{13}^2+d^2}$$

$$V_s=V_1+V_i-V_{12}+V_{23}-V_{13}$$

$$=\frac{\rho I}{2\pi L}\left(\ln\frac{L}{a}+\ln\frac{\sqrt{L^2/4+4d^2}+L/2}{2d}\right)-$$

$$\frac{\rho I}{\pi L}\ln\frac{\sqrt{L^2/4+d^2+S_{12}^2}+L/2}{\sqrt{d^2+S_{12}^2}}+$$

$$\frac{\rho I}{2\pi}\left(\frac{1}{S_{23}}-\frac{1}{\sqrt{S_{13}^2+d^2}}\right)$$

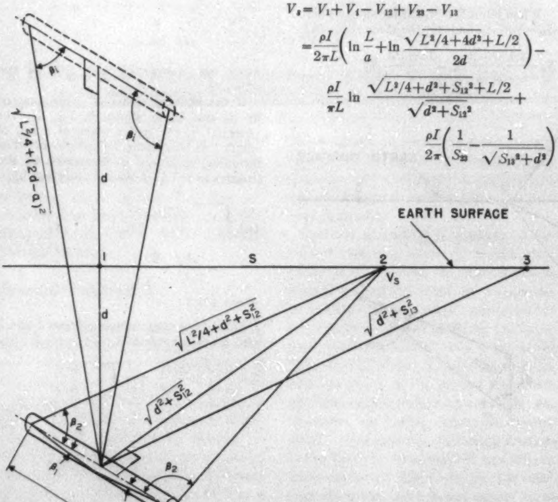

Fig. 12. Earth potential vectors for buried wire and its image

where $a\ll L$, and $a\ll d$

$$R_{(1-3)(1-2)}=\frac{\rho}{2\pi}\times$$

$$\left(\frac{1}{L}\ln\frac{L\sqrt{L^2/4+4d^2}+L^2/2}{2ad}-\right.$$

$$\frac{2}{L}\ln\frac{\sqrt{L^2/4+d^2+S_{12}^2}+L/2}{\sqrt{d^2+S_{12}^2}}-$$

$$\left.\frac{1}{\sqrt{S_{13}^2+d^2}}+\frac{1}{S_{23}}\right)$$

$$=\frac{\rho}{2\pi}\left(\frac{1}{L}\ln\frac{L^2}{2ad}-\frac{2}{L}\ln\frac{\sqrt{L^2/4+S_{12}^2}+L/2}{\sqrt{d^2+S_{12}^2}}-\right.$$

$$\left.\frac{1}{\sqrt{S_{13}^2+d^2}}+\frac{1}{S_{23}}\right)$$

where $d\ll L$

$$=\frac{\rho}{2\pi}\left(\frac{1}{L}\ln\frac{L^2}{2ad}-\frac{2}{L}\times\right.$$

$$\left.\ln\frac{\sqrt{L^2/4+S_{12}^2}+L/2}{S_{12}}-\frac{1}{S_{13}}+\frac{1}{S_{23}}\right)$$

where $d\ll S_{12}$

To show that equations 7 and 8 are fairly accurate for various lengths of buried wire, let

$$\frac{\rho}{2\pi}\left(\frac{1}{S_{23}}-\frac{1}{S_{13}}-\frac{2}{L}\ln\frac{\sqrt{L^2/4+S_{12}^2}+L/2}{S_{12}}\right)=0$$

or

$$\frac{1}{S_{23}}-\frac{1}{S_{13}}=\frac{2}{L}\ln\frac{\sqrt{L^2/4+S_{12}^2}+L/2}{S_{12}}$$

Let

$$S_{12}=XS_{13}$$

$$L=YS_{13}=ZS_{12}$$

where $Z=Y/X$. Therefore

$$\frac{X^2}{1-X}=\frac{2}{Z}\ln\left(\sqrt{Z^2/4+1}+\frac{Z}{2}\right)$$

Let

$$\frac{2}{Z}\ln\left(\sqrt{Z^2/4+1}+\frac{Z}{2}\right)=b$$

Therefore

$$X^2+bX-b=0$$

and

$$X=\frac{-b+\sqrt{b^2+4b}}{2}$$

Fig. 10 shows a curve of S_{12}/S_{13} for a range of values of L/S_{13}.

Discussion

G. F. Tagg (Evershed & Vignoles, London, England): The author has set out clearly one of the big difficulties in making accurate ground resistance measurements. In particular he has exposed the fallacy of obtaining more accurate results if the potential point is on the far side of the electrode from the current sink. On the other hand, it is only fair to remember that owing to variations in the resistivity of the soil, the proximity of topological features, and other factors, it is almost impossible to expect a very high degree of accuracy in measurements of this type. This being so, an application of the author's rule for distance may give no more accurate results than a measurement made in the usual way when the current and potential points are placed sufficiently far from the electrode under test for the resistance-distance curve to show a horizontal portion.

A paper of this kind is particularly valuable in drawing attention to the fundamental factors which underly this type of measurement. In dealing with very large distributed grounds it would, unfortunately, be almost impossible to apply the results of a theoretical investigation such as this, and recourse must be had to the practical rule of obtaining a horizontal section on the resistance-distance curve.

E. B. Curdts: Dr. Tagg has very properly emphasized the statement at the beginning of this paper that there is no theoretical substitute for actual field measurements of ground resistance. However, I am sure that we all agree on the desirability of a theoretical basis for all such measurements.

Since such measurements are ordinarily made with alternating or periodically reversing voltages rather than with direct voltages, the mathematical analysis in this paper lacks the rigor that would obtain on the basis of impedance paths rather than purely resistive ones. This may, in some instances, be one of the causes of the difference between theoretical and actual results.

One of the justifications for a theoretical analysis of the problem as given in the paper is the fact that some of the available publications on the subject convey, by implication at least, the idea that horizontal sections of the resistance-distance curves mentioned by Dr. Tagg are to be expected from a theoretical point of view.

The cost of making actual earth resistance measurements on very large ground grids can be appreciable, and anything done to provide a better understanding of the fundamentals involved should tend to reduce such costs.

The Technique and Instrumentation of Low-Impedance Ground Measurement

C. A DUKE
FELLOW AIEE

L. E. SMITH
NONMEMBER AIEE

THE MEASUREMENT of the impedance of grounding systems that have a value of less than one ohm and also residual ground currents flowing at the time of measurement requires special techniques and instrumentation. A summation of the quantities involved is given in this paper, with a description of a practical instrument that has been developed for making this type of measurement.

Measurement and Instrumentation Considerations

The impedance of a large-area grounding system is a vector quantity and can have a relatively large reactive component. Preferably the impedance is measured at system frequency, and the simplest method uses the voltmeter-ammeter arrangement.[1]

The instrument described in this paper is a specialized voltmeter-ammeter that responds to components of system frequency only. The instrument has internal circuits that are used to balance the voltages caused by residual currents. These two features permit ground-impedance measurements under difficult conditions by making negligible the chief sources of erroneous indication. The effects of mutual impedance between the test current and the resulting measured voltage must be avoided. This can be done best by taking the voltage readings along a physical line opposite in direction from the application of test current. If it is impractical to use opposite directions, fair results may be obtained at physical angles of 90 degrees between the current-probe direction and the physical line of voltage determinations. These precautions must be observed for low-impedance ground measurement regardless of the type of instruments used.

The effects of mutual impedance always increase the apparent value of ground impedance. The amount of increase varies with the ground resistivity of the area surrounding the ground system that is measured. As an example, on a representative large ground system when the current and potential test probes were placed in opposite directions, a value of 0.15 ohm was determined. When the probes were placed in the same direction, a value of 0.6 ohm was indicated. As a general rule a minimum of 0.3 ohm will be indicated with probes in the same direction, while the true value of the impedance of the ground system may be as low as 0.03 ohm. These differences may have a large economic value in the design of protection systems for communication facilities that are used at the grounding site. The rise of ground potential must be less than the breakdown of the communication protective gaps, or expensive neutralizing transformers must be installed in each communication line. When the possible ground fault current is very high, the difference between 0.1 ohm and 0.3 ohm for station ground impedance may be the deciding factor in determining whether extensive communication protective equipment is needed.

Determination of True Ground Impedance

The maximum value of voltage obtained divided by the test current in amperes gives the effective ground impedance. This gives the true value, provided the test-current probe location is at a greater distance from the center of the ground than the distance at which the maximum voltage is obtained. If

Paper 58-105, recommended by the AIEE Special Instruments and Auxiliary Apparatus Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2-7, 1958. Manuscript submitted October 17, 1957; made available for printing March 19, 1958.

C. A. Duke and L. E. Smith are with the Tennessee Valley Authority, Chattanooga, Tenn.

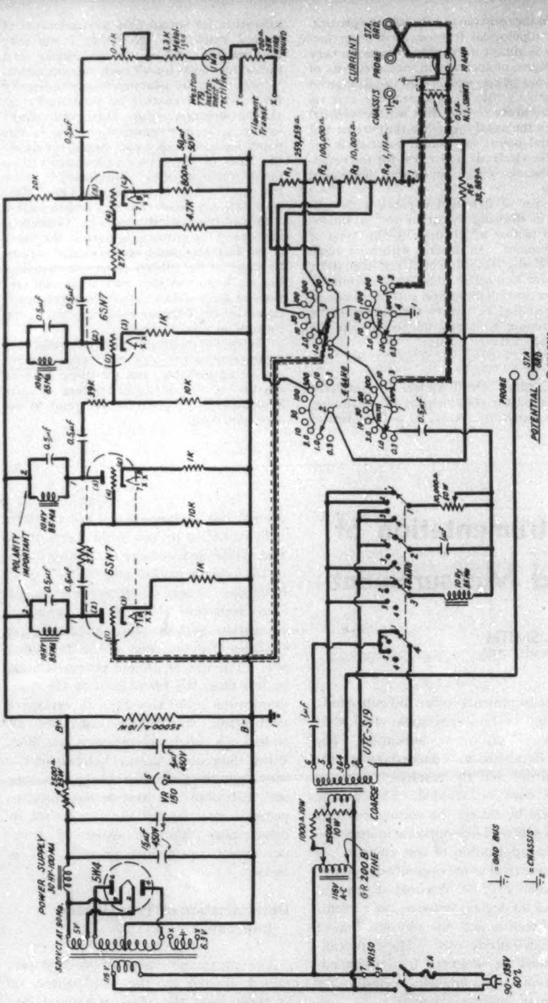

Fig. 1. Schematic wiring diagram of Selvaz

such is not the case, the test-current probe must be moved farther from the grounding system under test to a point of greater distance than that at which the maximum voltage is obtained, and the values must be redetermined. This redetermination is necessary to assure that the point from which the test current enters the ground is effectively at a remote location in relation to the grounding system under test. It is a very rare case that requires a distance of greater than 1,000 feet from the edge of even an extremely large grounding system for the location of the test-current probe, and this distance of 1,000 feet should be chosen for the initial test.

The plot of the ground impedance (volts divided by test amperes) against distance gives the effective potential gradient of the grounding system when the impedance is multiplied by actual or calculated ground-fault current.

Instrumentation Requirements

1. Residual Voltages

A substation grounding system usually has residual currents flowing into the system; these currents produce a corresponding voltage across the impedance of the ground. This voltage usually has fairly prominent harmonics. Also, around transmission lines carrying current, voltages may be induced in the test leads. The effects on the ground-impedance determination of these residual voltages must be made negligible.

2. Sensitivity

Values of less than 0.05 ohm for a large station ground impedance may be encountered, and adequate sensitivity must be provided when using a reasonable test current that has been selected arbitrarily at 10 amperes or less.

Actual Instrument Features

The effects of residual voltages are made small by balancing these residual voltages in the test circuit by introducing an equal but oppositely phased voltage, making the net voltage zero in the test circuit, with zero test current. This can be done only if a single-frequency component is considered, so the voltmeter amplifier is made frequency-selective to prevent interference by harmonics of the power line frequency. The response to the third harmonic is only 1%, with less response to higher harmonics. Even-numbered harmonics are rarely found as residuals, but these are rejected also by the voltmeter amplifier. The response to 120 cycles is 5%. The balancing voltage requirements are met with a 20-volt isolated source that can be varied smoothly from zero volts and can be shifted in phase through all angles by means of a quadrant switch and a continuously variable control for variation within each of the four quadrants.

The sensitivity requirements are met adequately, because the voltmeter has a minimum full-scale rating of 0.3 volt, with provision for scale multipliers so that voltages of at least 120 volts can be read to permit quick checking of accuracy in the field.

Need for Absolute Accuracy Eliminated

Since it is difficult to maintain absolute accuracy in a selective-frequency voltmeter that cannot use an inverse feedback amplifier for stabilization, provision is made for using the same amplifier and instrument to measure test current by measuring the voltage drop across a noninductive shunt. A small ammeter is used to monitor the current while the main instrument is measuring potential; thus the impedance (volts divided by amperes) will be indicated correctly, although the absolute indication of the instrument is in error. By using voltage regulation in the plate-voltage supply for the amplifier, the over-all maximum deviation from absolute readings is made relatively small: in the order of 1% over short periods and in the order of 5% from month to month.

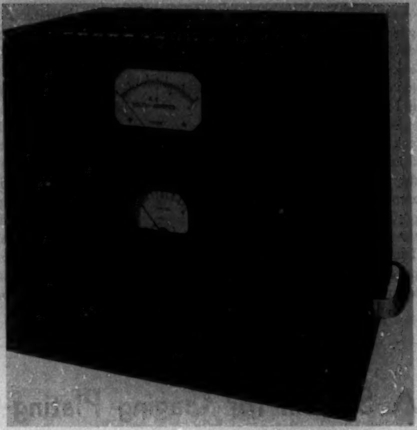

Fig. 2. Instrument used for ground-impedance measurement

Input Circuits

The input impedance to the voltmeter amplifier should be as high as practical so that the temporary potential test probe resistance to ground will have a negligible effect on the indicated voltage. In poor grounding locations the probe resistance may be as high as 3,000 ohms. In the final instrument the input impedance is 300,000 ohms; so no corrections need to be applied for probe resistance.

The terminal arrangements on the final instrument permit separate ground connections for the current and potential circuits. Common or mutual impedances of even short leads must be avoided when very low ground impedances are measured.

Detailed Features of Actual Instrument

The authors have coined the name "Selvaz" for this instrument from the designation term "*sel*ective frequency-*v*olt-*a*mpere-impedance (*Z*) meter."

A schematic wiring diagram is shown as Fig. 1, and the completed instrument is shown as Fig. 2. A simplified schematic of the instrument connections and the test ground connections is shown as Fig. 3. Note that two separate connections are made from the instrument to the station ground.

One of the design features of this instrument is the phase-shifting network shown in the lower left-hand corner of Fig. 1, which, when used with a variable-input-voltage isolation transformer, permits the introduction of a variable-magnitude-variable-phase voltage into the potential-measuring circuit. The residual voltage in the potential circuit can be balanced and made negligible; therefore the effect of the test current may be read directly on the voltmeter scale. The phase-shifting network consists of a quadrant switch that places in the circuit either a capacitor or a reactor with an associated variable resistor, with provision for reversing polarities. The phase shift is determined by the setting of the 10,000-ohm variable resistor. The range of the phase shift with the chosen values is 110 degrees, with an overlap on each of the quadrant ranges. A change of magnitude does not introduce a significant phase shift, nor does a change in the phase setting introduce a significant magnitude change when the circuit constants shown in Fig. 1 are used. It should be noted that the residual voltage is balanced directly before the potential-measuring circuit is involved. This permits changing voltmeter ranges without the necessity of rebalancing the residual voltage. With the circuit constants as given, about 20 volts of balancing voltage is available; this is adequate for any well-designed grounding system.

Proceeding further in the potential-measuring circuit, the 4-gang volt-ampere range switch is used to prevent sneak circuits between the current and potential circuits by means of the first and fourth gang. The second gang on this same switch, by cutting in the shunting 38,889-ohm resistor, gives a multiplier of 3 to the 1-, 10-, and 100-volt ranges; this simplifies the adjustment of the multiplying resistor string.

The selective-frequency amplifier constants were chosen to provide the maximum stability with maximum rejection to harmonics. Some degeneration is provided by not bypassing the cathode resistors in the tuned-plate stages. The reactors in the plate circuit of the first two stages are oriented so that the influence

of external magnetic fields is made negligible. Other circuits that do not use inductances in the selective-frequency circuits have been tried experimentally but have been found inferior to the one shown in Fig. 1.

With all the possibilities of extraneous voltages appearing in the amplifier circuit from either stray capacitances or stray flux fields, it is impractical to get a true zero response on the instrument when the potential input is short-circuited or when the range switch is set on "amperes." The simplest solution to this problem is provided in the final indicating instrument circuit, where a line frequency voltage is introduced in series with the indicating instrument. This voltage appears across the 100-ohm potentiometer-type rheostat provided from the center-tapped 6.3-volt winding of the amplifier power transformer. In operation the electrical zero of the indicating instrument is brought to true zero by means of this rheostat, while the range switch is set on amperes. This adjustment is not brought out on the panel, since usually a single setting is used on each instrument. Any internal residual voltage that may be present in the "volts" measuring position will be balanced manually and will not affect the measurement.

Conclusions

Five of these instruments have been in service for several years on the system of the Tennessee Valley Authority and have given very satisfactory results under difficult measurement conditions. The design features were developed because of specific requirements involved in making impedance measurements on extensive grounding systems.

A System for Gaging Plating Thickness

R. G. MYERS
ASSOCIATE MEMBER AIEE

D. L. WAIDELICH
FELLOW AIEE

THE NONDESTRUCTIVE measurement of cladding thickness when the cladding metal and the base metal are nonmagnetic has presented a major problem for a number of years. There have been several different approaches to the problem such as ultrasonics, back scattering of beta or gamma rays, and eddy currents. At present, the eddy-current method appears to have the greatest chance for success. Several eddy-current instruments have been developed, but there is still a need for improved instruments.

This eddy-current method utilized two different techniques in application. The first[1–2] employs sinusoidal eddy currents of a single frequency. This method uses comparatively simple, well-known techniques and instruments, but inaccurate phase measurements and thermal drifts are serious limitations. The second uses pulsed eddy currents containing a spectrum of frequencies. This method uses more complex techniques and instruments, but the phase measurement problem is eliminated, and the thermal problem created by current in the probe coil is minimized.

In the first pulsed eddy-current instrument,[3–5] the cladding thickness was read from the screen of a cathode-ray oscillograph. This instrument suffered from these disadvantages: it was not useful for continuously scanning a metal, and the coating thickness information was presented on the face of an oscilloscope and could not be recorded by a recording voltmeter. A second instrument[6] overcame these difficulties to some extent by the use of photocells placed on the screen of the oscilloscope. It was desirable, however, to eliminate the use of the oscilloscope and photocells if possible, and a new system for transferring the information to a recorder was developed. It is the purpose of this paper to describe this system and to present the results of tests made with it.

Operation

A small coil near the surface of a metal to be tested established a magnetic field in the metal, and this field induced eddy currents in the metal. The magnitude and direction of the eddy currents depends upon the coil geometry, the coil excitation voltage, the distance from the coil to the metal, and the resistivity of the metal. A change in cladding thickness is a change in resistivity. The impedance of the coil changed with a change in the magnitude and direction of the eddy currents.

A small ferrite-cored coil with its axis perpendicular to the surface of the metal was used to project the field into the metal. The coil windings were concentrated near the end of the probe to obtain maximum sensitivity to a given change in coating thickness. A cross section of the probe is shown in Fig. 1. When the cladding thickness changed, the impedance of the coil changed. To obtain the cladding thickness information, this change in coil impedance was measured with the aid of a bridge circuit.

The bridge circuit in Fig. 2 was excited by discharging a charged capacitor through the thyratron. When the input pulse from the pulse generator triggered the thyratron the 1,000-$\mu\mu f$ (micromicrofarad) capacitor discharged through a pulse-shaping network and the primary of the transformer. This provided a bridge excitation pulse shaped like the positive half of a sinusoidal wave. The secondary of the transformer was loosely coupled to the primary and shielded from the primary.

The pulse projected into the coated metal should meet certain length requirements. The length is directly related to the basic time.[3]

$$T=t^2\mu_1\sigma_1$$

where t is the coating thickness. Representative values of T are given in Table I. For best results, the input pulse from the probe should be approximately five times

Fig. 2. System circuit diagram

T. From Table I this would necessitate an extreme range of pulse lengths. Some compromise is necessary unless only one coating thickness and coating metal is to be used.

If a slight unbalance is present, an unbalanced voltage exists at the bridge output terminals. A standard sample of metal was placed on one probe, and another sample of metal was placed on the other. Balancing adjustments on the bridge were made, and the bridge output voltage was nearly zero. An unbalance was added by changing the test probe air gap, and the output voltage pulse was as indicated in Fig. 3(A). One major difficulty was variation of the bridge output voltage with probe-to-metal spacing. It was discovered experimentally that one point on the bridge output pulse did not vary in amplitude with the probe-to-metal spacing as indicated in Fig. 3(B). This point will be called the crossing point. The amplitude of the crossing point does vary with the cladding thickness.[6]

Table I. Values of T

Coating Metal	T Microseconds Coating Thickness 5 Mils	25 Mils
Aluminum	0.75	18.8
Zirconium	0.045	1.12
347 stainless steel	28.1	702.0

An analysis of the bridge circuit was made to show that the crossing point does exist. The details of the analysis are given in the Appendix, and the results are shown in Fig. 4, where e_0 is the bridge output voltage and K' is a constant which does not change the shape of the curves. There was one point on the calculated curves that did not vary with the probe-to-metal spacing and this checked with the experimental results indicated in Fig. 3(B).

To determine the cladding thickness, a sample of the bridge output voltage had to be taken at the crossing point. The sampling technique, in other words the technique for separating the probe-to-metal spacing information and the cladding thickness information, will be described in the next two sections.

The Sampling Pulse

To generate a sampling pulse, an *884* thyratron was operated as a switch to discharge a charged transmission line through the characteristic impedance of line as indicated in Fig. 2. The pulse from the bridge circuit and the sampling pulse were synchronized by firing both thyratrons with one pulse generator. The sampling pulse was positioned in time by a variable delay line in the grid circuit of the thyratron.

The duration t_0 of the sampling pulse was calculated from the value of the total storage capacitance C_s and the characteristic impedance R_0 of the line. The network was assumed lossless and was charged to a voltage E. The ampli-

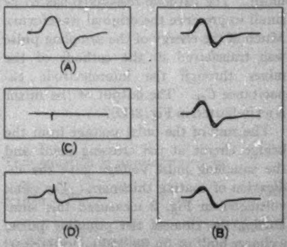

Fig. 3. Waveforms from cathode-ray oscilloscope

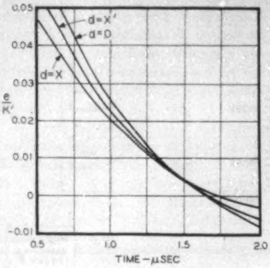

Fig. 4. Calculated bridge output voltage

tude of the pulse was $E/2$. Since the energy originally stored in the capacitance C_s was delivered to the load resistance R_0 during discharge

$$\frac{1}{2} C_sE^2=\left(\frac{E}{2}\right)\left(\frac{E}{2R_0}\right)t_0$$

or $t_0=2R_0C_s$

The duration t_0 for 9 inches of *RG-58/U* coaxial cable was 2.29×10^{-9} second.

The actual pulse shape and length were largely determined by the *884* thyratron. The ionization time was about 10×10^{-9} second and this increased the length of the pulse. The deionization time of the *884* had a very small effect on the pulse length. The transmission line discharged very rapidly, and when the plate voltage dropped to zero, the tube extinguished. Fig. 3(C) shows the sampling pulse. The pulse length was about 15×10^{-9} second and the amplitude was approximately 15 volts.

Mixer and Voltmeter

The mixer in Fig. 2 summed the bridge output pulse and the sampling pulse. The high input impedance reduced the interaction of the two pulses to a minimum. The cathode resistance has to be small to preserve the original waveforms. Much of the energy of the sampling pulse was transferred to the cathode of the mixer through the interelectrode capacitance C_{gk}. The output of the mixer is as indicated in Fig. 3(D).

The sum of the pulse voltage from the bridge circuit at the crossing point and the sampling pulse voltage gave the indication of coating thickness. The peak voltmeter in Fig. 2 measured this sum. During the time of the sampling pulse, a charge built up on the 150-μμf capacitor. During the off part of the cycle the charge decayed at a rate given by the time constant of the capacitance and the input resistance of the *6SF5* triode. Since the input resistance of the *6SF5* was very large, the time constant for the decay was very large, and the charge on this capacitor decayed very slowly. As a result, the peak of the sampling pulse was measured with no interference from the peak of the bridge output pulse. The difference amplifier in Fig. 2 provided a high gain and a simple method for balancing out the direct voltage that contained no coating thickness information. With a proper selection of voltmeter, the coating thickness can be read directly in mils. The results for nonmagnetic stainless-steel-coated on brass are given graphically in Fig. 5 where d is the probe-to-metal spacing. It should be noticed that the readings are nearly independent of the probe-to-metal spacing.

One difficulty experienced was a seemingly random variation in the output indication. The use of regulated power supplies helped this considerably, but there was still a small amount of the random variation left. It is probable that further work on the supplies would eliminate most of this difficulty.

Conclusions

The calculated bridge output voltage indicated the presence of the crossing point. The major error in the calculation was introduced by the probe characteristic assumptions. A true equivalent circuit for the probe has not been found, and this will have to be done before exact calculations can be made.

This eddy-current instrument measures cladding thickness fairly independent of probe-to-metal spacing. Pulsed eddy currents have one major advantage over sinusoidal eddy currents: a much higher peak current can be applied to the probe coil without heating the coil if the proper pulse length and repetition rate have been selected. The one major disadvantage of this pulse system is that the pulses must be very stable in amplitude and time.

Appendix

Bridge Circuit Analysis

The equivalent circuit of the bridge circuit and bridge circuit pulser is shown in Fig. 6(A). The voltage e was calculated by replacing the transformer and the bridge with an equivalent circuit which was found by measuring the input impedance at the transformer primary. Then the equivalent circuit is as shown in Fig. 6(B).

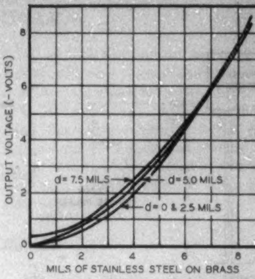

Fig. 5. Output of entire system

The expression for the Laplace transform of the voltage e is

$$\mathfrak{L}(e)=\frac{\left(\frac{1}{R_1C'}\right)E_0S}{S^3+\left(\frac{1}{R_1C}+\frac{1}{R'C'}+\frac{1}{R_1C'}\right)S^2+\left(\frac{1}{R_1R'CC'}+\frac{1}{C'L'}\right)S+\frac{1}{R_1CC'L'}} \quad (1)$$

Substituting circuit values

$$\mathfrak{L}(e)=\frac{3.46\times10^6\,E_0S}{S^3+9.15\times10^6S^2+12.76\times10^{12}S+9.35\times10^{18}} \quad (2)$$

The Laplace transform of the primary current is

$$\mathfrak{L}(i_p)=\frac{1}{L'S}\,\mathfrak{L}(e) \quad (3)$$

After substituting equation 2 into equation 3 and taking the inverse Laplace transform, the primary current i_p is

$$i_p=1.67\times10^{-3}E_0\epsilon^{-0.755\times10^6t}\times \sin(0.806\times10^6t-6.8°) \quad (4)$$

for $t\geqq0.3$ μsec (microsecond). The Laplace transform for the approximate primary current i_p is:

$$\mathfrak{L}(i_p)=\frac{-0.197\times10^{-3}E_0S+1.19\times10^3E_0}{[(S+0.755\times10^6)^2+(0.806\times10^6)]^2} \quad (5)$$

The resistances R_1 and R_2 were assumed small enough to be neglected. The 10-kilohm resistances may be neglected, because they are large compared to the 1-kilohm resistances. The large input resistance R_d of the mixer was neglected.

With the bridge balanced, the voltage equation for the secondary is

$$0=M\frac{di_p}{dt}+L_s\frac{di_2}{dt}+i_2Z \quad (6)$$

where Z is the entire bridge impedance, and

$$Z(s)=\frac{2LRS}{RCLS^2+LS+R} \quad (7)$$

The Laplace transform of equation 6 was solved for the Laplace transform of the

secondary current. Multiply by $Z(s)$ to obtain

$$\mathcal{L}(e_2)=\frac{-MS\mathcal{L}(i_p)Z(s)}{L_sS+Z(s)} \tag{8}$$

The circuit values were substituted in equation 5 and the inverse Laplace transform was used to obtain

$$\frac{e_2}{K10^{-9}}=9.8\epsilon^{-0.756\times10^{6}t}\sin(0.806\times10^{6}t+46.6^{\circ})+88^{-6.45\times10^{6}t}-1630^{-31.6\times10^{6}t} \tag{9}$$

where

$$K=0.394\times10^{-3}\frac{ME_0}{L_sC}$$

This equation is approximated by

$$\frac{e_2}{K10^{-9}}=45\epsilon^{-0.9\times10^{6}t} \tag{10}$$

or 0.5 μsec ≤ t ≤ 2.0 μsec. The Laplace transform of equation 10 is

$$\frac{\mathcal{L}(e_2)}{K10^{-9}}=\frac{45}{S+0.9\times10^{6}} \tag{11}$$

The bridge circuit was drawn as indicated in Fig. 6(C). Let the voltage e_s be any applied voltage, and e_0 the output voltage. The mixer input resistance was assumed to be 10^6 ohms. The loop equations were

$$-e_s=20\times10^3 i_1-10\times10^3 i_2 \qquad (12)$$

$$0=-10^4 i_1+(10^4+10^6+Z_2)i_2-Z_2 i_3 \qquad (13)$$

$$e_s=-Z_2 i_2+(Z_1+Z_2)i_3 \qquad (14)$$

These equations were solved for the current i_3, and i_3 was multiplied by the mixer input resistance to obtain

$$e_0=\frac{10^6(Z_2-Z_1)e_s}{2Z_1Z_2+2.01\times10^6(Z_1+Z_2)} \qquad (15)$$

The Laplace transform of this equation is

$$\mathfrak{L}(e_0)=\frac{10^6[Z_2(s)-Z_1(s)]\mathfrak{L}(e_s)}{2Z_1(s)Z_2(s)+2.01\times10^6[Z_1(s)+Z_2(s)]} \qquad (16)$$

where

$$Z_i(s)=\frac{\frac{1}{C}S+\frac{R_i}{L_i}}{S^2+\frac{R_i}{L_i}+\frac{1}{RC}S+\frac{R_i+R}{CL_i}} \qquad (17)$$

The probe characteristics are assumed to be $L_0=200$ microhenrys, and $R_0=50$ ohms in air. From previous sinusoidal investigations,[1] the probe inductance and resistance varied with a change in probe-to-metal spacing according to $L=L_0-\Delta L$, and $R=R_0+\Delta R$, where $\Delta R=K\Delta L$ and K is a constant.

Let L_1 and R_1 equal L_0 and R_0 respectively. Let it be assumed that a metal is close to probe 2, and that the probe characteristics for three different probe-to-metal spacings are as follows:

d	$L_2(\mu h)$	$R_2(\Omega)$
0	120	80
X'	130	75
X	140	70

These values were substituted in equations 16 and 17. Let equation 11 be the applied voltage function. This was substituted in equation 16 in place of the Laplace transform of any voltage function e_s. The inverse Laplace transform was taken and for $d=0$,

$$\frac{e_0}{K'}=-0.105\epsilon^{-0.403\times10^6t}+0.236\epsilon^{-0.9\times10^6t} \qquad (18)$$

where $K'=\frac{-45}{K10^{-6}}$

for $d=X'$

$$\frac{e_0}{K'}=-0.081\epsilon^{-0.373\times10^6t}+0.192\epsilon^{-19\times10^6t} \qquad (19)$$

for $d=X$

$$\frac{e_0}{K'}=-0.059\epsilon^{-0.352\times10^6t}+0.151\epsilon^{-0.9\times10^6t} \qquad (20)$$

These equations are plotted in Fig. 4.

Stand-by Power for Pole-Mounted Equipment

D. F. JAMIESON
NONMEMBER AIEE

THE APPLICATION of a stand-by power system to pole-mounted equipment involves a great deal more design effort than the conventional telephone battery plant.

In the normal telephone exchange, the battery and charger can be closely supervised and maintained with ease. Equalizing charges can be accomplished at frequent intervals, and specific gravity readings can be taken, over a period of time, without difficulty. The temperature variations experienced by a normal telephone exchange battery plant are not more than ±30 F (degrees Fahrenheit) from room temperature and published discharge curves predict the battery behavior during an a-c power interruption. All of these conditions help to keep the battery at its top efficiency.

To power pole-mounted equipment, the stand-by battery plant has to perform under conditions never experienced by the normal telephone exchange:

1. The battery has to be mounted on a pole, adjacent to the equipment it will have to power.
2. The temperatures experienced in pole-mounted equipment may vary 180 F, that is, from −40 to 140 F.
3. Servicing of the battery plant will have to be kept to a minimum, due to the inaccessibility of the equipment located at widely scattered points, many miles from the central office.
4. Water additions to the battery will not be easily accomplished in most cases and should not be required except on a semiannual basis.
5. Available charge and discharge curves do not give any indication of the battery's characteristics when operating in this environment.

These problems started an investigation into the type of stand-by power which could be used to provide emergency service for pole-mounted equipment. Particular emphasis in this paper is given to powering a new transistorized 5-channel Subscriber Carrier System, known as the *561* Carrier System.

561 Subscriber Carrier Power Requirements

Fortunately, for the power equipment designer, the *561* Carrier System is transistorized. This fact alone means that the power requirements, during an a-c service interruption, will be considerably less than conventional vacuum tube equipment.

For example: The idle channel drain of a subscriber terminal is, on a d-c basis, only 5 watts. When the channel is in use, its power drain increases to 10 watts.

Paper 58-851, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 18, 1958; made available for printing April 11, 1958.

D. F. Jamieson is with Stromberg-Carlson Company, a Division of General Dynamics Corporation, Rochester, N. Y.

The author wishes to acknowledge the assistance of J. E. Ross, who supervised the mechanical design; Henry Jenson of the C & D Battery Company for the use of data on the lead calcium batteries; and R. L. Layburn, S. B. Weiner and H. C. Behnk of Stromberg-Carlson who assisted in the preparation of this paper.

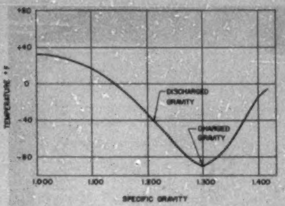

Fig. 1 (left). Freezing points of aqueous solutions of sulphuric acid at various gravities

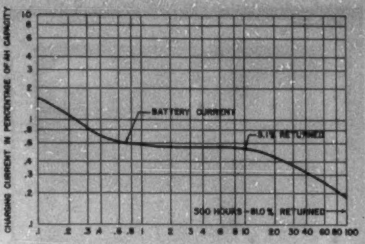

Fig. 3 (right). Typical lead calcium battery specific gravity 1.300 constant voltage charge at 2.35 volts/cell at −40 F

Most of this additional energy goes to power the subscriber's telephone. Peak power requirements during the signaling interval does not exceed 25 watts. Stand-by power supplies capable of meeting such low power requirements are numerous. Many types of stand-by power supplies were investigated in connection with this development. The most promising types are listed, with a short description of their advantages or limitations.

TYPE OF STAND-BY POWER SUPPLIES

Solar Cells. A rather new development, the Solar Cell represents a possible solution to the problem of powering transistorized equipment. However, a battery plant will still be required to cover the night-time power drain. Efficiency is still too low for this application.

Atomic Batteries. Several types are available today; however, their output is too low even for this application. Shelf-life of the order of 20 years makes them highly desirable.

Dry Batteries. Many different types of dry batteries could be used. Mercury cells offer the greatest advantage with regard to shelf-life and low temperature. Disadvantages of dry batteries will be discussed further in this paper.

A-C Battery Charger and Battery Plant. This is the present-day method used in telephone exchanges. However, the battery is extremely sensitive to environmental conditions.

SERVICE REQUIREMENTS FOR STAND-BY POWER

The questions of how much stand-by power should be available and what type of telephone service would be required during a power failure were investigated. When a power failure occurs in the normal telephone exchange, the telephone subscriber is in many instances unaware that anything has happened. His telephone service continues uninterrupted.

The telephone subscriber served by a subscriber carrier system, on the other hand, will in all probability experience a power failure in his own home at the same time power is cutoff the channel equipment. This fact makes it doubly important to maintain telephone service during a power interruption. Since the telephone subscribers would undoubtedly inform the power company of the service interruption, a short battery discharge time was contemplated. With a stand-by power supply designed for a 2-hour discharge period, many power failures would be provided for; however, prolonged power failures could cause considerable difficulties with customer relations. A short discharge period gave impetus to the use of one-shot devices such as dry batteries. The replacement of the batteries after a power failure would be necessary in order to provide reliable service and could be accomplished only if the telephone company was aware that a power failure had occurred. When it is considered that the telephone company may have as many as 100 subscriber carrier channels in operation, the service requirements are tremendous and the battery replacement cost is extremely expensive. Under these considerations, the use of dry batteries is not practicable.

In the normal telephone exchange, experience has shown that about 98% of the service interruption can be handled by an 8-hour discharge period, and rechargeable batteries can be used for periods as long as 20 years. Based on this information, it was decided to provide an a-c charger and rechargeable battery of high quality to power the *561* Carrier System.

ECONOMICS OF STAND-BY POWER

In order to minimize the cost to the operating company of the stand-by power supply, the requirements were established on the basis of two groups:

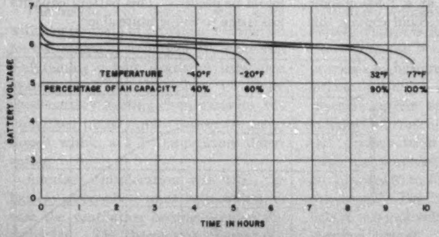

Fig. 2. Typical lead calcium battery specific gravity 1.300 constant current discharge to 1.84 volt/cell

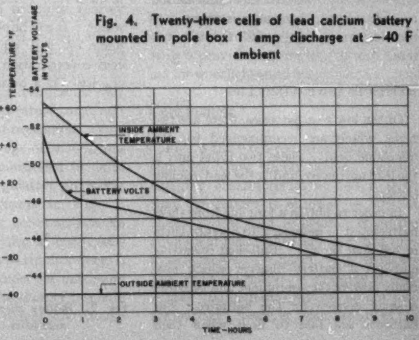

Fig. 4. Twenty-three cells of lead calcium battery mounted in pole box 1 amp discharge at −40 F ambient

Fig. 5 (left). Laboratory setup used in environmental testing of batteries, charger, and insulated housing

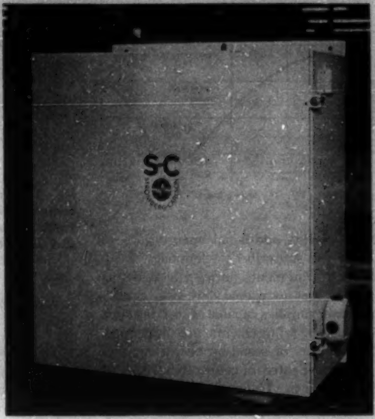

Fig. 6 (right). Engineering model of stand-by power supply housing

Group 1. A battery and charger capable of powering five subscriber terminals for an 8-hour discharge period.

Group 2. A battery and charger capable of powering one subscriber terminal (with provision for growth to three terminals) for an 8-hour discharge period.

This grouping enabled the designer to take advantage of types of batteries already in high production and make a considerable saving in cost. The grouping of the power requirements also indicated that for a single terminal power source, the cost analysis should consider the growth factor. This is necessary because the single terminal itself could not be expected to support the standby power supply. In special cases where standby power is required for only the single channel, it would be necessary to plan the installation with this growth in mind. This can be accomplished easily with the *561* Carrier by concentration of the terminals. For further information on this subject, the reader is referred to the literature on the *561* Carrier System.[1-3]

BATTERIES AND BATTERY LIFE

Of the low cost batteries, there are two types which are recommended for the telephone field. These two types are: 1. the lead antimony, and 2. the lead calcium battery.

In order to obtain a long life from these batteries, it is necessary to operate them in full float service. Full-float operation employs a battery charger which normally powers the equipment and provides a small current for the batteries. The batteries are said to float when their internal losses are compensated for and the battery voltage is raised to the gassing voltage. In this operation, the charging current is very low and, as a result, long life can be expected from the batteries.

Once the basic power system was decided upon, the problems of low temperature operation of the lead antimony battery and the lead calcium battery were considered.

LOW TEMPERATURE OPERATION OF LEAD ACID BATTERIES

The main problems of operating batteries at low temperature are:

1. The battery once it is discharged will freeze.
2. The battery ampere-hour capacity is reduced.
3. Recharging the battery after an 8-hour discharge period requires an extremely long period of time.

Fig. 1 shows the freezing points of various solutions of sulphuric acid and water. It will be observed that the lowest point on this curve occurs when the acid concentration is at a 1.300 specific gravity. If a battery could contain this high-gravity acid, it would freeze at approximately −85 F. A lead antimony battery containing this high acid concentration would have a very short life. The lead calcium battery, on the other hand, could handle this concentration without any ill effects. This would mean that a lead calcium battery could not freeze, buckle its plates, crack its container, or the like, at a temperature of −40 F since its discharged gravity would still be higher than 1.240 after an 8-hour discharge period. Going to a higher acid concentration than 1.300 would allow the discharged gravity to fall to the 1.300 point. Higher acid concentration would, however, shorten the life of even a lead calcium battery. Thus, a compromise was made and the battery was established to be composed of lead calcium cells at a 1.300 specific gravity.

Discharge curves of a 1.300 gravity lead calcium battery shown in Fig. 2 indicates that in order to provide the power requirements over the low temperature range, a battery of 60% more capacity would be needed. This battery capacity loss is due to temperature alone.

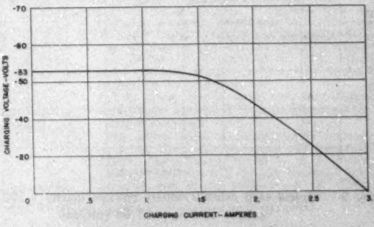

Fig. 7. Battery charger characteristics

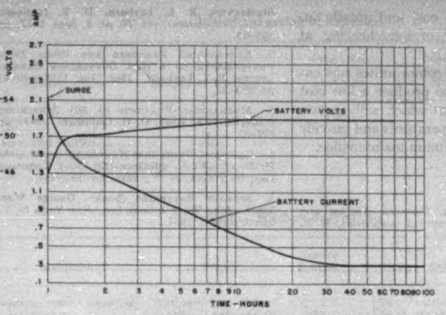

Fig. 8. Twenty-three cells of lead calcium battery mounted in pole box charge characteristic at 140 F

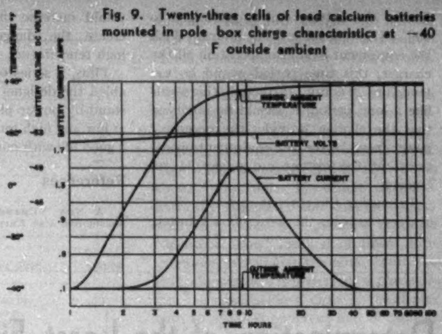

Fig. 9. Twenty-three cells of lead calcium batteries mounted in pole box charge characteristics at −40 F outside ambient

The charging characteristics of the lead calcium cell at a temperature of −40 F, Fig. 3, indicates that approximately 500 hours will be required to return the battery to 81% of its capacity. Since a stand-by power source requiring 500 hours to recharge would be useless for the *561* application, a source of heat would have to be provided.

Battery Housing Design

Because it is necessary to provide heat for the batteries in low temperature operation, the battery housing must contain a heater. In order to reduce the size and power drain of the heater, it is necessary to equip the housing with a thermostat and insulate the box to reduce the heat loss. Thus, when a power failure occurs, the heat in the battery housing plus the heat stored in the batteries will provide a good 8-hour discharge characteristic; see Fig. 4.

The battery problem might seem to be solved merely by sealing and heating the battery housing. This proved misleading. Those familiar with lead acid batteries know that hydrogen gas is given off during the charging and floating periods and ventilation is required to prevent an explosion.

The mechanical designer was faced with the problem of providing ventilation for the escape of hydrogen gas while still maintaining a high degree of insulation against heat loss. In order to insure good battery floating characteristics, the individual battery cells had to be maintained within a 5 F temperature differential.

Another consideration was that the battery atmosphere must be sparkless, in case the ventilation became accidentally restricted. The thermostat, charger disconnect relay, and all possible sparking points are, therefore, enclosed. Ventilation for the housing is accomplished by small holes located in the bottom, and at the top side of the box; see Figs. 5 and 6. Because of the vent hole placement, gas escape is assured and the heat loss is limited to that through the top vent.

The box itself is insulated with fiber glass insulation with an aluminum reflecting surface. The heater, a strip type, insulated with Teflon to prevent acid damage, is located in the bottom of the box. The batteries are arranged above the heater on a perforated shelf in two steps, and on a solid shelf near the top with the charger.

This arrangement is such that air through the bottom vent is heated and is forced to circulate around the batteries. The air is forced, by its own rising characteristics when it hits the solid shelf, to circulate throughout the box. With this design, it is possible to maintain the battery temperature differential to within 5 F.

Power System Layout

The power plant consists of 23 cells of lead calcium battery, designed to float at 2.30±0.05 volts per cell. The battery charger will parallel the battery and hold the battery voltage at 52.9±1 volt. The battery charger is designed to operate over the −40 to 140 F temperature range and provide a high degree of regulation. Variations on a-c line voltage of ±10% and charging current are controlled by both voltage and current regulators producing the characteristics shown in Fig. 7. Taps are provided to accommodate an a-c range of 95 to 130 volts, 60 cps (cycles per second). The 120-cps ripple voltage is held to 300 millivolts under the maximum charging current. The charger response time to changing loads is held slow enough so as not to produce noise in the *561* Carrier System.

Power Plant Maintenance

The problems of maintenance for both the battery and charger were paramount in the mind of the designer. The battery is easily accessible both for specific gravity readings and water additions. The charger circuitry employs the use of long-life components. Silicon power diodes are used to remove the problem of aging adjustments on rectifier stacks and to reduce the size of the units. Either magnetic or transistor regulation was recommended in order to eliminate the maintenance difficulties of vacuum tube control.

The charger, at present, has one adjustment for float voltage; however, this adjustment will be removed in later design and will eliminate the possibility of overcharging due to improper voltage measurement or adjustment. The use of zener diodes for reference elements has greatly reduced the variation of voltage with temperature and will allow the charger circuitry to be set at the factory. Water addition to the batteries is usually not necessary, except in extremely hot climatic conditions. An a-c accessory strip is provided within the battery housing for worklights and instruments.

Conclusions

Figs. 8 and 9 represent the results of the stand-by power supply design. Battery charging characteristics at 140 F show that the battery is returned to 80% of charge in less than 10 hours. When the equipment load is also included, this time is extended to 20 hours. Fig. 9 shows that when the battery is charging at −40 F only 100 milliamperes can be put into the battery; however, with the aid of the heater, the battery can be recharged to 80% of its capacity in 15 hours. With the equipment load also operating off the charger, this time period would be extended to 20 hours. Although, this seems like a long period, it should be observed that the charger provides the necessary power to make the *561* equipment operational at the instant a-c power is reapplied.

Increasing the current capacity of the charger, to bring the battery back faster, would increase the cost and greatly increase the danger of overcharging at high temperature.

Thus, a series of compromises has enabled the designer to produce a low cost stand-by power plant which will operate at low and high temperatures and provide a good life with minimum maintenance.

Determination of the Least First Cost of a Cable-Carrier System

ROMAN KRZYCZKOWSKI
NONMEMBER AIEE

IN THE MIDDLE of 1956 a study was made of the economics of providing a cable-carrier system along one of the principal railway routes in England. The route was to be electrified by a 25-kv 50-cps single-phase system which made impossible the continued use of existing overhead telephone lines.

A clean field for complete modernization of the telecommunication system was thus opened. As a result, the technical necessity of introducing suitably screened cable was coupled with the opportunity of providing a substantial increase in general communication facilities, so essential for the best use of the improved efficiency of an electrified railway system.

This paper describes the method adopted in the part of the study devoted to the determination of the Least First Cost of the proposed system. Some of the results and conclusions arrived at in the study are quoted.

Problem and Assumptions

Cable-carrier communication was required along a 160-mile long route. The initial capacity of this system was to be approximately 100 telephone channels and the ultimate capacity in the neighborhood of 400.

The broad examination of the problem in the light of past experience showed that it could be limited to a comparison of implementing required connections by either of the following methods:

1. 12-channel, 2-wire
2. 24-channel, 2-wire
3. Single tube coaxial

In examination of postulated carrier-cable systems the following elements have had to be taken into account:

1. Cable and its method of installation
2. Terminal equipment
3. Line equipment
4. Power feeds

Appropriate combination of these elements gave an optimum economic solution.

It was assumed that irrespective of the trunk circuits to be provided by carrier methods, some vf (voice frequency) pairs would be required for local circuits, supervisory pairs, etc. These vf pairs could be either incorporated together with the carrier quads or coaxial tubes in one cable in the form of one or more layers of audio pairs or, alternatively, separate vf cables could be provided

Carrier quads could be provided in either 40 pounds (lb)/mile or 25 lb/mile gage; vf pairs in either 40 lb/mile or 20 lb/mile gage. With cables laid adjacent to a 25-kv a-c electrified track adequate screening from induced voltages had been provided.

In accordance with railway requirements all telecommunication cables had to be placed in one concrete troughing laid along the track. Allowance for loading of all vf pairs and for appropriate cable accessories were included. Spacings of repeaters for different systems of working are shown in Table I.

It was assumed that reliable power supplies are available in all future repeater sites and therefore power feeding was not contemplated. For coaxial schemes allowance was made for suitable voltage regulators.

Method of Analysis

Altogether the study examined three carrier systems using two kinds of cable; the study allowed for two different gauges and for various quantities of vf and carrier pairs. Combinations of the above parameters required the inclusion of 28 different cables.

It is clear that all possible permutations of the above parameters would give a very large number of theoretically possible solutions. Hence a methodical step-by-step method was introduced for the analysis of the problem. Its logical basis can be formulated as follows. It is considered that the following parameters are at play and can be changed:

1. Number of cables, n
2. Size of cables, s
3. Additional facilities, f
4. Simplified techniques, t

Every one of these parameters is in turn dependent on at least three variables:

Price of copper, x
Price of lead, y
Other functions determining the cost of a system, z

If Q = total first cost of a system then

$$Q = F(n,s,f,t) \qquad (1)$$

and as each of the parameters in equation

Paper 58-905, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 19, 1958; made available for printing April 25, 1958.

Table I. Spacing of Repeaters

System	Method of Working	Conductor Gage, Lbs/Mile	Repeater Spacing, Miles	No. Required
12 channel carrier	2 wire	40 25	20 17	7 9
24-channel carrier	2 wire	40 25	12 9	13 17
Coaxial	Single 0.375-inch tube		6	27

Table II. Method of Analysis

Movement	Step	Carrier System	Cables Used	Combination
Starting point: what railways want	Evaluate the cost of original railways requirements (4 separate cables)	12	24 pr. carrier 40 lb 54 pr. trunk 40 lb 24 pr. trunk 40 lb 24 pr. trunk 40 lb	1 ↓
Diminish number of cables	Combine 24 pr. carrier and 54 pr. trunk	12	24/40c+52/40t 24/40t 24/40t	2 ↓
	Combine 24/40 and 24/40 trunks	12	24/40c+52/40t 54/40t	3 ↓
	Use *one* cable	12	24/40c+118/40t	4
Diminish size of cable	Use 20 lb for vf	12	24/40c+148/20t	5
	Use only 14 pr. for carrier circuits	24	14/40c+116/20t	6 ↓
	Use only one tube for carrier circuits	Coaxial	0.375-inch tube+120/20t	7 ↓
	Reduce number of vf pairs from 120 to 68	Coaxial	0.375-inch tube+68/20t	8
Give additional facilities	Separate carrier from audio	Coaxial	0.375-inch tube 54/20 trunk	9 ↓
	Give separate remote control cable	Coaxial	0.375-inch tube 54/20 trunk 6/20 trunk	10 ↓
	Increase number of vf pairs	Coaxial	0.375-inch+68/20t 6/20 trunk	11 ↓
	Use 40 lb gage for control cable	Coaxial	0.375-inch+68/20t 6/40 trunk	12
Simplify techniques	Substitute 24 channel for coaxial	24 channel	14/40c+52/20t 6/20 trunk	13 ↓
	Use vf for some medium length links, i.e., 40 lb gage	24 channel	14/40c+40/40t 6/20 trunk	14
Further increase facilities	Offer vf pairs in two cables	24 channel	14/40c+52/20t 24/20 trunk	15 ↓
	Offer some vf pairs in 40 lb gage	24 channel	14/40c+52/20t 24/40 trunk	16 ↓
	Give separate control cable	24 channel	14/40c+92/40t 6/20 trunk	17

c = carrier pairs
t = vf or trunk pairs

1 is a function of variables x, y, and z, then:

$$\begin{aligned} n &= F_1(x,y,z) \\ s &= F_2(x,y,z) \\ f &= F_3(x,y,z) \\ t &= F_4(x,y,z) \end{aligned} \qquad (2)$$

where $F_1, \ldots F_4$ are the respective functions.

The problem is to find the true minimums of equation 1. As the total differential from equation 1 is:

$$dQ = \frac{\partial F}{\partial n}dn + \frac{\partial F}{\partial s}ds + \frac{\partial F}{\partial f}df + \frac{\partial F}{\partial t}dt \qquad (3)$$

we can examine the problem methodically by keeping at a time all parameters but one constant, and varying the one under investigation. The influence of this variation on the total outlay is then observed. Equation 3 is thus the logical basis of the method employed.

As there are four parameters, four principal "movements" or variations in respective parameters, are examined:

1. Diminish number of cables—i.e. vary n
2. Diminish size of cables—i.e. vary s
3. Give additional facilities—vary f
4. Simplify techniques—vary t

Altogether 17 combinations are examined. In every case the layouts of the cables used are dictated by technical requirements of stranding.

The analysis starts from the original requirements suggested by the railway authorities:

1 carrier cable suitable for 12-channel working, 24 pairs/40 lb

1 long distance vf cable, 54 pairs/40 lb

1 short distance (local) vf cable, 24 pairs/40 lb

1 remote control cable, 24 pairs/40 lb

The total first cost of the preceding cables placed in concrete troughing, jointed, loaded, and brought into service, plus the cost of terminal and line equipments, gives the starting datum point. This is labelled combination 1.

Every movement is carried out in several steps. Thus the movement "Diminish number of cables" is done in four steps resulting in four combinations. The whole sequence of the analysis is shown on Table II which diagrammatically illustrates the adopted logical analysis. While it is realized that the "transportation" method of linear programming would give the same result, the way adopted here is preferred, as throughout the calculation a clear physical picture of result is apparent and nothing is left to the mechanism of tabulation. The position might have been different with a greater number of variables.

It is to be noted that carrier systems become the dependent function of the cable parameter. Thus the movement "Diminish size of cable" (in combination 6 and 7) requires the transformation of carrier techniques from 12 channels into 24 channels and coaxial respectively. A deliberate effort to consider the system as an independent parameter is made in combinations 13 and 14, which are the variations of t.

When it is required to find the influence of variables x, y, z on the total first cost, equation 1 can be expanded into:

$$\begin{aligned}
\frac{\partial Q}{\partial x} &= \left(\frac{\partial Q}{\partial n}\right)\left(\frac{\partial n}{\partial x}\right) + \left(\frac{\partial Q}{\partial s}\right)\left(\frac{\partial s}{\partial x}\right) + \left(\frac{\partial Q}{\partial f}\right)\left(\frac{\partial f}{\partial x}\right) + \left(\frac{\partial Q}{\partial t}\right)\left(\frac{\partial t}{\partial x}\right) \\
\frac{\partial Q}{\partial y} &= \left(\frac{\partial Q}{\partial n}\right)\left(\frac{\partial n}{\partial y}\right) + \left(\frac{\partial Q}{\partial s}\right)\left(\frac{\partial s}{\partial y}\right) + \left(\frac{\partial Q}{\partial f}\right)\left(\frac{\partial f}{\partial y}\right) + \left(\frac{\partial Q}{\partial t}\right)\left(\frac{\partial t}{\partial y}\right) \qquad (4) \\
\frac{\partial Q}{\partial z} &= \left(\frac{\partial Q}{\partial n}\right)\left(\frac{\partial n}{\partial z}\right) + \left(\frac{\partial Q}{\partial s}\right)\left(\frac{\partial s}{\partial z}\right) + \left(\frac{\partial Q}{\partial f}\right)\left(\frac{\partial f}{\partial z}\right) + \left(\frac{\partial Q}{\partial t}\right)\left(\frac{\partial t}{\partial z}\right)
\end{aligned}$$

Equation 4 was not directly used in the study but this formulation was at the back of investigation into risks involved in copper and lead price variations (variables x and y). It also served to show the lack of economic justification for using concrete troughing (variable z).

Results

Fig. 1 shows that all combinations examined offer respectively about 400 circuits, carrier and vf, when fully utilized. Starting capacities are near the 200 mark. Expansion possibilities of systems vary between 170% and 240% depending on

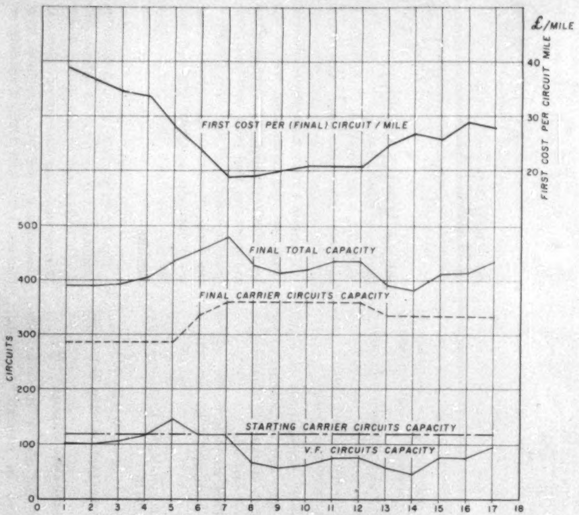

Fig. 1. Capacities and costs per circuit per mile

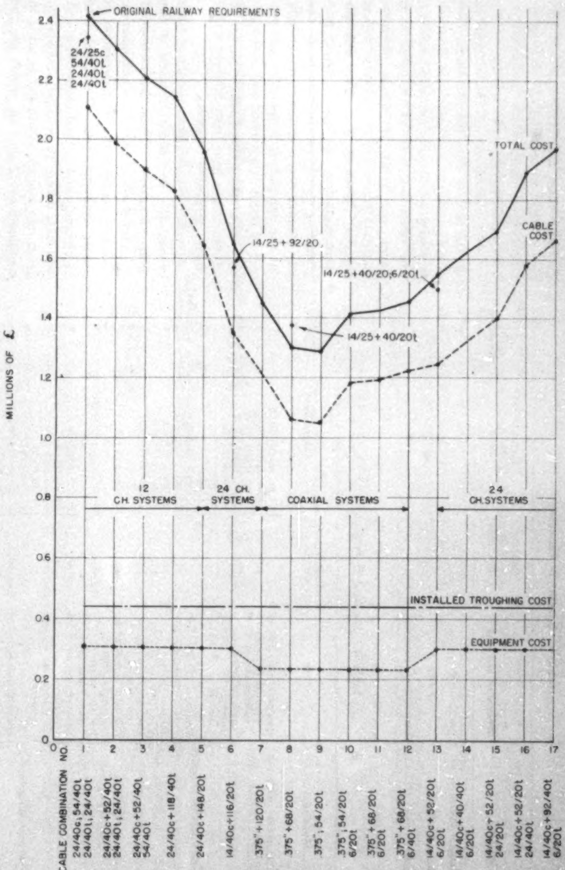

Fig. 2. Total costs

cable sizes. Coaxial solutions are found in that respect to be the most flexible. Detailed data on which Fig. 1 is based is given in Table III.

Fig. 2 shows the build-up of costs and to draw attention to their singular composition the first costs of two combinations (1 and 9) are drawn pictorially in Fig. 3. It is observed that by adopting coaxial carrier techniques the first cost of cables can be very appreciably reduced. The main difficulty in the further lowering of these costs is the outlay on troughing which remains fixed irrespective of the system adopted, and which in the least first cost solution, combination 9, is almost equivalent in magnitude to the cost of cables, while far exceeding the total outlay on equipment. Tables IV and V give the first costs of the combinations examined.

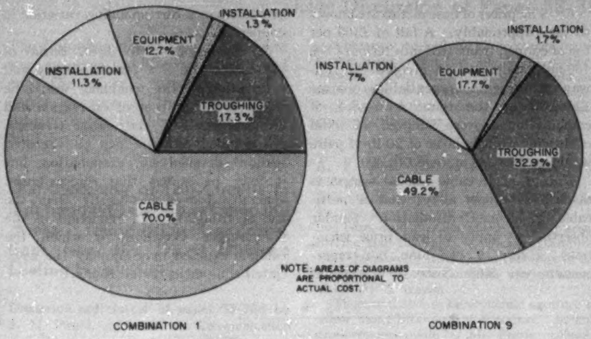

Fig. 3. Build-up of first costs

Table IV. First Costs of Systems Examined

Combination No.	Carrier System	Cables Used	Cost: Cables Per 1,000 Yards, £	Cost: Cables Per 158 Miles, £	Cost: Equipment, £	Total First Cost, £
1	12 channel	24/40c 54/40t 24/40t 24/40t	7,532	2,110,000	310,000	2,420,000
2	12 channel	24/40c+ 52/40t 24/40t 24/40t	7,133	1,995,000	310,000	2,305,000
3	12 channel	24/40c+ 52/40t 54/40t	6,788	1,900,000	310,000	2,210,000
4	12 channel	24/40c+ 118/40t	6,534	1,830,000	310,000	2,140,000
5	12 channel	24/40c+ 148/20t	5,813	1,650,000	310,000	1,960,000

7	coaxial	0.375-inch+120/20t	4,340	1,215,000	235,000	1,450,000
8	coaxial	0.375-inch+68/20t	3,805	1,065,000	235,000	1,300,000
9	coaxial	0.375-inch tube 54/20t	3,758	1,050,000	235,000	1,285,000
10	coaxial	0.375-inch tube 54/20t 6/20t	4,227	1,180,000	235,000	1,415,000
11	coaxial	0.375-inch+68/20t 6/20t	4,274	1,195,000	235,000	1,430,000
12	coaxial	0.375-inch+68/20t 6/40t	4,398	1,225,000	235,000	1,460,000
13	24 channel	14/40C+52/20t 6/20t	4,497	1,260,000	300,000	1,560,000
14	24 channel	14/40c+40/40t 6/20t	4,753	1,330,000	300,000	1,630,000
15	24 channel	14/40c+52/20t 24/20t	4,984	1,400,000	300,000	1,700,000
16	24 channel	14/40c+52/20t 24/40t	5,690	1,590,000	300,000	1,890,000
17	24 channel	14/40c+92/40t 6/20t	5,960	1,670,000	300,000	1,970,000

Table V. First Costs of Systems Employing 25-Lb Carrier Conductors

Carrier System	Cables Used	Cost of: Cables Per 158 Miles, £	Cost of: Equipment, £	Total First Cost, £
12 channel	24/25c 59/40t 24/40t 24/40t	2,000,000	340,000	2,340,000
24 channel	14/25c+92/20t	1,240,000	330,000	1,570,000
24 channel	14/25c+40/20t	1,045,000	330,000	1,375,000
24 channel	14/25c+40/20t 6/20t	1,170,000	330,000	1,500,000

Conclusions

1. The least cost solutions are obtained by using coaxial carrier techniques, the least number of cables, and an absolute minimum of vf pairs.

2. For the three carrier techniques under comparison the first costs of terminal and line equipment are broadly similar, and from other studies it is known that this is broadly true within limits for lengths of line 50–500 miles, and for circuit capacities 100–1,000 telephone channels. Expenditure on equipment forms about one fifth of the total expenditure and hence savings on equipment cannot have a decisive influence on the over-all outlay.

3. The cables under consideration offer approximately either 50 or 100 vf pairs to be used for local and control circuits. Some pairs will be definitely required and one layer, that is approximately 50 pairs is the smallest practicable quantity to be incorporated in a composite cable. The cost of the next 50 pairs increases the cost of any system by approximately £1,000 per mile.* Thus from the first cost point of view there is a strong case for reducing the number of vf pairs to one layer only, and engineering most of the connections as carrier circuits even for relatively short distances.

4. Economies available on account of diminishing the number of cables are in the order of £2,000 per mile when one composite cable only is employed instead of four separate ones.

5. The first cost of the convenience of having 40 lb/mile vf conductors instead of 20 lb conductors is broadly £600 per mile for the first layer (about 50 pairs)

---

* A pound (£) is presently worth $2.80.

and £1,300 per mile for the next 50 pairs. These figures contain the additional expenditure on lead sheathing and armouring of cables of larger diameter.

The cost advantage of 25 lb gauge of carrier conductors is the greatest when 24/40 carrier conductors are replaced by smaller gage in conjunction with a 12-channel system. The cost advantage is then in the order of £600 per mile. Fig. 2 shows however that no significant economies are obtained in the region of the least cost solutions. Twenty-five lb/mile conductors are not competitive enough for coaxial tubes.

6. The prices of base metals are known to vary appreciably. A fall of £100 per ton of copper, translated into terms of the 160-mile route, would involve the railway authorities in a potential loss of some £150,000 on the route concerned, if combination 1 were adopted. Coaxial cable with a single layer of 20 lb vf pairs would entail a loss of some £40,000.

Thus a single cable coaxial system is much less "copper risky" than a multicable 12-channel installation. Similar observations apply to lead price variations. Every £ per tone has repercussions on cable costs several times greater than a corresponding variation in copper price.

7. By resorting to direct burial of the cables, the cost for the supply and installation of the troughing would be replaced by the cost of excavation and reinstatement of the cable trenches. No detailed estimate can be ventured without detailed site examination, but it may be stated that direct burial generally proves less costly than the use of troughing and reduction of the temperature variation to which the cable is exposed may simplify the associated equipment requirements.

◆

Discussion

G. Rezos (The Pacific Telephone and Telegraph Company, San Francisco, Calif.): This is a very interesting and unusual method for deciding which is the best plan to use for a new cable carrier system.

There are a few points which need clarification:

1. The time interval between the "starting" capacity and the "final total" capacity should be specified. If it is a slow growing system, we can justify a very expensive ultimate layout, if we can defer high cost items for a long time. Then we can save large amounts in interest, carrying charges, depreciation reserves, etc.

For a fast growing system, where we must spend our money over a few years, low overall cost becomes all-important. In other words, *when* we spend the money is just as important as *how much*, and the when may become controlling. Early expenditures have much more effect than later ones. Also, to compare several plans we should have equal starting capacity. Hence it seems risky to compare combination 5 (starting with 268 circuits) with combination 9 (174 circuits) even though their final total capacity is about the same (436 and 414). We would have to spend a lot of money earlier on combination 9 to make it match combination 5.

2. Table IV shows equipment costs for all combinations to be roughly the same. While this may be true when any combination reaches its final total capacity, it does not seem reasonable for the initial costs. The "get started" costs for a small number of coaxial circuits is generally very much higher than that for a few 12-channel cable carriers.

3. Intangible factors must be considered. In the coaxial plans, the failure of a single repeater element could disable all through circuits; with several 12-channel cable carriers a complete failure from equipment troubles is much less likely. On the other hand, a complete break in the cable itself would affect coaxial and cable carriers equally.

4. The decision between direct burial of the cables or troughing could have a major effect on the choice of lowest cost combinations. A direct buried cable must be much larger because it must last many more years than cables placed in conduit. In conduit, cables can be added at economic intervals; with direct burial the hazards of burying a second cable near the first may be out of question. The greater first cost of the larger buried cable may completely override the effects of other variables.

Roman Krzyczkowski: Mr. Rezos is quite right in pointing out the danger of limiting economic studies to first cost considerations only. "*When* we spend the money is just as important as *how much*" is one of the best formulations of the problem I have ever seen.

I deal rather fully with this subject in another paper[1] and, incidentally, I point out there that inflation is yet another factor which necessitates taking *time* into consideration.

The present paper describes only a fragment of a complete economic study. This fragment is concerned with the determination of the least first cost—as the title of the paper implies—and not with final decision: which is the best plan to use for a new cable carrier system. Other parts of the study, apart from calculations of (time) capitalized costs, dealt also with intangibles, which, as Mr. Rezos rightly points out, are of decisive importance.

I agree that the choice between direct burial of the cables and troughing makes a fundamental difference in first costs. The decision to put cables in troughing was arrived at from consideration of intangibles, such as safety, reliability, and maintenance.

European and American prices are different and consequently it is misleading to make direct dollar comparisons. For that reason original figures are left in pounds sterling and pounds weight and are not expressed in dollars and wire gages. Also, it is the primary purpose of the paper to describe a method of determining the least cost. According to my experience, as soon as the "get started" capacity is in the order of one full International Consultative Committee on Telegraphy (CCIT) supergroup, initial costs of a coaxial and of 4-wire multicore cable installations break even. This appears to be confirmed by reference 2.

Late Discussion of Paper 58-386

The following discussion and closure were received too late to be published with the paper; they are included herein because of the similarity of subject matter to the preceding paper 58-905.

Dial Switching of Toll Circuits in Independent Telephone Company Areas: Transmission Considerations from the Direct Distance Dialing Standpoint

Discussion and closure of paper 58-386 by J. N. Petrie, published in Communication and Electronics, September 1958, pages 481–85.

E. E. Nelson and **George Rezos** (The Pacific Telephone and Telegraph Company, San Francisco, Calif.): In reference to the paper by J. N. Petrie, we would like to discuss the following considerations.

1. The paper assumes the continued use of CDO (community dial office) tandem points. It proposes "tail-eating" switching at such points (class *5-A*). We are basing our plans on getting rid of tandem CDO operation as soon as possible to avoid transmission problems, as well as dialing problems such as limited stop-go features in outgoing crossbar tandem senders. The change from tandem CDO operation would not be done by itself; it would be combined with some major change to reduce costs.

2. Balancing problems are also involved in switching the line and network leads. To avoid unbalances, the line and net leads should have the same resistance and capacity. The net leads should follow the same path through the office as the line, including the path through the trunk circuits. Quadded switchboard cable will probably be necessary, using one side for line and the other side for net. Repeating coils in the trunk circuit should be matched in the net path. The physical location of the balancing equipment could become troublesome.

3. In normal circuit order work involving jumper cross connections, tip and ring turnovers will have to be watched closely to combine the power in the tandem hybrid coils.

4. The 4-db (decibel) loss of the hybrid will be obtained in the terminating condition (3-db division of power + 1-db copper, core, and wiring loss). The 1-db loss of the hybrid in the through condition should be compensated by line and net pads in the switching train. The pads, relays, and control circuits could run into quite a bit of space and complexity.

5. Extra contacts are required on all switches in the toll train. Class *4* offices with toll switchboards would require 4-wire switching. In the class *5 A* offices a large part of the 4-wire switches would be connecting a compromise network to the hybrid.

6. The "tail-eating" scheme was attractive when first proposed many years ago because we had to interconnect many 2-wire trunks to a few 4-wire (or carrier) trunks. Now, with most toll circuits on carrier, and the increasing use of carrier even for very short hauls, the advantages gradually disappear.

A. F. Rose (American Telephone and Telegraph Company, New York, N. Y.): Tail-eating switching as described in Mr. Petrie's paper is not new in principle. It has been used in Australia and other areas for the last 15 years. I assume, therefore, that the novelty involved in this case is the Automatic Electric Company version known as the *FW-1* system.

There will always be economic pressure to allow more links in a toll connection, and the proposal made by Mr. Petrie probably involves less transmission sacrifice than would be likely if 2-wire switching of the ordinary type were used. However, I feel he has underestimated the transmission penalty, as Bell System experience shows that transmission variations added by each link are presently considerably exceeding the 0.4 db anticipated when the via net loss factors were established. Also, it should be borne in mind that an additional link at one end of the connection may also involve one at the other end.

I am glad to see that Mr. Petrie appreciates the problems of PBX (private branch exchange) transmission and compares his proposal for the *5 B* office to the use of a PBX trunk as an extra link in the toll chain. This agrees with our thinking but we feel that as direct distance dialing is established into and out of PBX's we may have to treat them as end offices in some cases and home them on suitable higher ranked offices. Some large PBX's in the Bell System are already being handled in this manner, and this serves to improve rather than degrade transmission to these important customers.

In some of Mr. Petrie's illustrations, "return loss" objectives are indicated. It is not clear at what point in the switching office these figures apply. In Bell System usage we refer to return loss measured at the switches. We find that the average return loss of loops against a compromise network is 11 db with a sigma of 3. If a measurement were made at the hybrid through a 5-db pad this would be 11 db + 2 × 5, or 21 db. On the other hand, if the intention is to measure at the switch points, 20 db in a class 5-office is somewhat better than our experience would indicate to be realizable.

Finally, it seems worthwhile to point out that spending the extra capital to provide this type of switching does not completely eliminate the maintenance attention needed to keep office balance up to its original value. Unbalance can occur even under the tail-eating scheme, and reversal of tip and ring may have more serious consequences.

In bringing these problems to the attention of the independent companies, I believe Mr. Petrie has made a considerable contribution. However, I hope that they will understand that adding links to a toll connection adds transmission loss even with the best switching system and should be resisted unless an economic study shows substantial savings. Where we have studied similar cases, the cost advantage has favored direct circuits from the *5B* office to the toll center instead of special switching equipment. With the continuing downward trend in the cost of carrier facilities this is even more likely to be true in the future.

J. N. Petrie: The six considerations contained in the discussion by Mr. Nelson and Mr. Rezos are all quite pertinent. My comments will take up each in turn.

1. From the Bell System point of view there can be no argument with the philosophy expressed by these gentlemen; they seem to have missed the point, however, of some of my remarks in the opening paragraphs that: "The problem of complying with transmission requirements of the general toll switching plan, and also of fitting into classifications established for them, is particularly difficult for many independent telephone companies." Why this is so is discussed in the next two paragraphs following the one from which the quotation was taken. To "legitimize" this situation would require the Bell System to upgrade many class *4* (toll center) offices to class *3* (primary center) offices.

2. All of the problems mentioned under this heading have been recognized and have been solved, essentially as suggested, in the *FW-1* switching scheme which is described in several of the references included in the original paper.

3. This is not a jumper or cross-connection problem as the 180 degree phase reversal is handled automatically by the switching equipment.

4. There is no argument with the several points raised. Nevertheless, I am reliably informed that the space and circuit complexity problems are no greater than with other 4-wire switching schemes.

5. Four-wire switching at class *5A* offices, on the basis suggested in the paper, does not necessarily require 4-wire switching at the class *4* (toll center) office. Figs. 5 and 6 show the two alternatives. It is true that the switches at a *5A* office would be connecting a compromise network part of the time. This is one of the advantages of the system proposed since it permits each switch to be made under the most favorable conditions and does not commit a whole office to be built-out (at great cost and with recurring high maintenance) to a compromise condition. The implication seems to be that the 4-wire switches would be too costly. On this point I am informed that the extra cost for 4-wire switches versus 2-wire switches is of the order of 10%, which, it would appear, would be very reasonable for the gains and benefits derived.

6. Whether the advantages of the tail-eating connection are gradually disappearing will depend on the switching philosophy which a company may adopt. Certainly, for the smaller trunk groups, typical of most independent companies, there are advantages in being able to terminate or to tandem switch indiscriminately all carrier circuits, regardless of make, different transmission levels, and circuit impedances at the 4-wire points. The tail-eating techniques of switching do offer this advantage.

In reply to the very pertinent comments by Mr. Rose, I would like to point out that the pressure for the switching arrangement proposed is not primarily economic but rather of an administrative nature. This results largely from the need of many independent companies to operate a "community of interest" telephone network with toll center functions concentrated at a class *5A* office. The proposed arrangement recognizes this situation and suggests a means of meeting the established toll transmission requirements in spite of the tandem switch added at the *5A* office.

The comments with respect to the return losses shown are entirely valid. It is, however, a fact that the insertion of pads, as indicated, was only partly prompted by return loss considerations; in fact, the values chosen were primarily dictated by gain switching requirements. The pads do have the effect of improving the return loss at the hybrid coil terminals, thus making gain switching possible.

It is recognized that the successful operation of the tail-eating switching scheme presupposes symmetry of circuits through an office but this is not in the same sense that office balance is a problem at 2-wire intertoll switching points. The reversal of the tip and ring conductors is no problem since the switches introduce the necessary 180-degree phase reversal. An accidental reversal introduces such effective transmission blockage that it should be no problem to locate.

There can be no agrument with Mr. Rose's statement that direct circuits from the end office to the toll center (class *4*) may have cost advantages. As stated earlier, the switching scheme under discussion is being proposed primarily to solve an administrative problem.

A Triple-Action Positioning Controller Using a Magnetic Modulator

C. V. BULLEN
NONMEMBER AIEE

THIS PAPER describes a process control of the triple-action positioning type; i.e., the control circuits provide variable proportioning, automatic reset, and rate actions to position a valve or other modulating device. The input or error signal is derived from a recording instrument of the null-balance type, which can be a potentiometer recorder operating from a thermocouple, a self-balancing resistance thermometer, or a pressure recorder operating from a strain-gage transducer.

The novel feature of this control circuit is the use of a magnetic modulator, whose purposes are

1. To add the error signal and the various feedback signals.
2. To convert the sum into an a-c signal which can be amplified readily to control the valve position.

The magnetic modulator assembly (Fig. 1) consists of a pair of transformers each having five windings. The core material is a high nickel alloy selected for a rapid change in permeability with a change in saturation. Corresponding windings on the two cores are connected in series. One pair of windings is connected to a 60-cycle-per-second source to provide excitation. A second pair of windings provides the output voltage. These windings are connected in series opposition so that, with no current in the control windings, the voltages from the two windings are equal and opposite and the net output from the modulator is zero. A third pair of windings carries a direct current which biases the cores to a steep part of the permeability curve. The fourth and fifth pairs of windings are control windings. Each pair of control windings is polarized so that a current in it adds to the bias mmf (magnetomotive force) in one core and subtracts from it in the other. Thus, the permeability of the core with the lower net mmf is higher and the voltage induced in its output winding predominates over the voltage in the output winding of the core which has the greater net mmf.

The magnetic modulator assembly is shown in Fig. 2. A somewhat simplified diagram of the complete control is shown in Fig. 3.

The error signal is derived from an auxiliary slide wire in the null-balancing instrument. The drum carrying the resistance winding is mounted on the main shaft of the recorder, while the slider position is adjustable for selection of control point. The slider mounting arrangement is such that the slider contacts the center of the resistance winding when the recorder registers the desired temperature. Control winding *1* of the magnetic modulator is connected from this slider to the center connection of two equal resistors connected in series across the same 8-volt source that energizes the auxiliary slide wire. Thus, when the recorded temperature is at the desired control point, the current through this control winding is zero. When the recorded temperature departs from the control point setting, an error current, varying in polarity and magnitude with the direction and degree of departure, flows in control winding *1*. This causes an a-c signal to appear at the output of the magnetic modulator. This signal is amplified by a 2-stage voltage amplifier and applied to the paralleled grids of a phase detector. The plates of the phase detector, with relays in series, are connected to opposite ends of a transformer secondary so that the supply voltages for the plates are 180 degrees apart in phase. When a signal is applied to the grids it will be in phase with the plate supply voltage of one of the triodes and a current will flow in the corresponding relay. The relay contacts control the operation of the motor which positions the valve or other modulating device.

The combination of magnetic modulator, voltage amplifier, and phase detector thus causes the valve to open or close whenever the recorder indication deviates below or above the desired control point.

The motor which drives the valve also drives a slide wire which is energized by the 8-volt source. The slider voltage, which indicates the valve position, is applied to one grid of a balanced cathode follower through a series capacitor *C1*. The output voltage of the cathode follower is connected to control winding *2* of the magnetic modulator. Normally, when the recorded temperature has been at the desired value for some time, both grids and, therefore, both cathodes are at the same potential and no current flows in control winding *2*. A balance adjustment is provided at the ground end of the cathode resistors to assure this condition regardless of inequalities in the two sections of the tube.

If the controlled temperature drops, an error current is caused to flow in control winding *1* and the valve motor is caused to run in the opening direction. The potential of the slider of the valve slide wire rises toward ground and the change in voltage is applied through *C1* to the left grid of the cathode follower. The potential of the left cathode rises by an almost equal amount and thus causes a current to flow in control winding *2*. As the valve continues to open, this current increases until it eventually equals that in control winding *1*. Since the mmf due to currents in the two control windings oppose each other, as soon as the current in winding *2* equals that in winding *1*, the output of the magnetic modulator drops to zero and the valve motor stops. The amount of valve motion necessary to accomplish this rebalance after a given deviation from the desired temperature can be varied by adjustment of a rheostat in series with control winding *1*. This rheostat is calibrated in per cent proportional band which is the temperature deviation in per cent of full recorder scale divided by the resulting valve motion in per cent of full travel, the quotient also being expressed in percentage. In

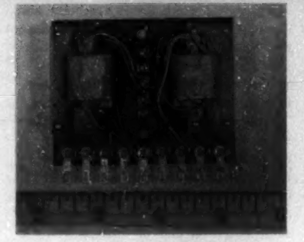

Fig. 2. Magnetic modulator

this control the proportional band may be adjusted through a range of 2% to 200%.

The type of control described in the foregoing is known as proportional control and is characterized by a corrective action proportional to the error. It allows control without hunting but usually results in the controlled condition being maintained at some value other than desired. This is the control point shift associated with straight proportional control. To avoid this shift it is necessary to introduce resetting, also known as floating or integral control. In this type of control, the amount of correction is proportional to the time integral of the error.

Capacitor *C1* starts to charge to the potential of the valve slider and, as it charges, the potential of the left grid of the cathode follower falls back toward zero. The current in control winding *2* drops, upsetting the balance previously obtained in the modulator. This results in a further small corrective motion of the valve. As capacitor *C1* continues to charge, periodically unbalancing the modulator, the valve continues to inch along, always in the same direction as the initial motion. The average rate of valve motion is determined by the time constant of *C1* and the adjustable resistor *R1*. The reset rate is expressed in repeats per minute, which is the average valve rate in degrees per minute divided by the initial valve motion (due to proportional action) in degrees, assuming a constant error. In this control, reset rate is adjustable between 0.06 and 100 repeats per minute.

The resetting action continues until the error has been reduced to zero and *C1* has fully charged to the slider potential, reducing the potential of the left grid of the cathode follower to zero.

To minimize overshooting, it is desirable to introduce a third type of control in which valve motion is a function of rate of change of error. This introduces a

correcting factor which adds to, or subtracts from, the effect of the error magnitude. The rate correction is introduced at the right grid of the cathode follower by the differentiating network *C2*, *R2*. The effect of this connection is to apply a potential at the right grid which is a function of the rate of change of error voltage. For example, if the error is positive and rising, a negative potential is applied to the right grid. This makes it necessary for the valve to move further in the closing direction to rebalance the modulator than it would if the velocity component were absent, and the overshooting tendency is reduced.

Rate effect is measured by per cent of valve movement per per-cent per minute of recorder rate. The units work out to be minutes. In this control rate times of up to 5.5 minutes can be obtained by adjustment of *R2*.

The reset and rate circuits are essentially the same; in each a varying voltage is connected to a resistor and capacitor in series, with an output voltage taken from across the resistor. However, the actions of the two circuits are quite different because of differences in time intervals and time constants. In a circuit of this configuration:

$E_0 = KRC(1-\epsilon^{-t/RC})$ when $E_1 = Kt$

where

E_1 = input voltage (across resistor and capacitor in series)

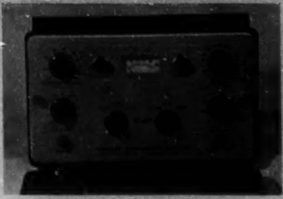

Fig. 4. Panel of control unit

E_0 = output voltage (across resistor)

K = rate of change of input voltage, volts per second

R = resistance, ohms

C = capacitance, farads

t = time after input voltage starts to change, seconds

$\epsilon = 2.7183$

In the reset circuit, a typical value for *RC* is 800 seconds, whereas the valve motor may run 10 seconds or less to rebalance the circuit. The ratio t/RC is thus very small and under this condition $E_0 = Kt$ very nearly. Therefore, the output voltage is practically the same as the input voltage.

In the rate circuit, a typical value of *RC* is 5 seconds. The input voltage may continue to rise for minutes. Where t is several time constants $E_0 = KRC$ very nearly and, therefore, the output voltage is a linear function of the rate of change of input voltage.

Fig. 5. Control unit mounted on recorder

A valve position meter consisting of a voltmeter connected from closed end to slider of the valve slide wire is provided. Auxiliary switches allow the valve to be positioned manually when desired.

Fig. 4 shows the panel of the control unit. It is ordinarily mounted below the recorder, as shown in Fig. 5. The door of the control has an opening which exposes only the controls necessary for starting and shutting down the system. When the control door is closed and the recorder door locked, none of the critical adjustments are accessible to unauthorized persons.

A Quadruplexer Allowing the Simultaneous Transmission of Two Complete Television Stations Using a Common Antenna

G. B. MacKIMMIE
NONMEMBER AIEE

IN THE SPRING of 1956, the need arose in Quebec City to add a new English-language television station in order to supplement the existing service of CFCM-TV, in operation on channel four, and serving primarily the predominant French-speaking population.

The transmitting facilities of CFCM-TV consisted of a 5-kilowatt transmitter, and a 3-bay superturnstile antenna mounted on a 500-foot self-supporting tower. In the interest of greatest efficiency and economy, the owners were anxious to make maximum use of existing facilities in planning the new station, which later became known as CKMI-TV and which operates on channel five. A plan was therefore evolved which included use by the new station of the existing antenna and feed system, with no alteration, and without affecting in any way operation on channel four.

In order to accomplish this result, a "quadruplexer" was designed and constructed. The quadruplexer provides a means of interconnecting the four transmitters, two aural and two visual, to the antenna feed system with no interaction among the transmitters. Furthermore, since the antenna reflections are not insignificant at the frequency of the new channel, special provisions are incor-

Paper 58-904, recommended by the AIEE Television and Aural Broadcasting Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y. Manuscript submitted Nov. 6, 1957; made available for printing May 12, 1958.

G. B. MacKimmie is with the RCA-Victor Company, Ltd., Montreal, Que., Canada.

The author wishes to acknowledge gratefully the contributions of his associates. The skill and perseverence of B. Berridge and H. Hings in the design and development of this quadruplexer contributed vitally to its success. In addition, the kind co-operation of the owners and engineers of CFCM-TV and CKMI-TV during installation and final testing is greatly appreciated.

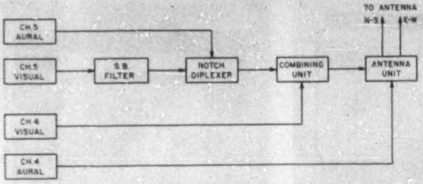

Fig. 1. System block diagram

porated within the quadruplexer to absorb channel five antenna reflections and thus to prevent the radiation of a ghost signal. It should be noted in passing, that, though channels four and five are numerically adjacent, there is actually a spacing of 4 megacycles (mc) between them, and therefore assignment of both in a city is permissible. Channel four covers a frequency range from 66 to 72 mc and channel five from 76 to 82 mc.

It is the purpose of this paper to describe the quadruplexer, which has now been installed successfully and has been in commercial operation since March 1957.

General Description

The basic elements of the quadruplexer are shown in the block diagram, Fig. 1. The channel five visual signal, after passing through a vestigial sideband filter, is combined with the channel five aural signal in the notch diplexer, the first element of the quadruplexer. The single output of the notch diplexer feeds one input of the combining unit, which also receives at another input the channel four visual signal. The output of the combining unit is delivered to the antenna unit, which also receives the channel four aural signal, and delivers the complete dual-channel signal to the antenna transmission lines. Since the antenna is of the turnstile type, all north-south radiating elements are brought together and fed from one line, while all east-west elements are similarly fed from a second line. To obtain nondirectional radiation from the antenna, the east-west line is made 90 electrical degrees longer or shorter than the north-south line in the usual way.

The antenna unit incorporates the channel five reflection absorption device mentioned previously. If this feature had not been provided, there would have been excessive ghost radiation on channel five, since the measured voltage standing wave ratio due to the antenna termination on this channel is in excess of 1.2. On channel four there is, of course, no reflection problem, since the antenna was originally designed and erected for operation on channel four.

Circuit Description

Having outlined the composition of the quadruplexer in its three essential parts, the notch diplexer, the combining unit, and the antenna unit, there will follow a brief description of each of these units. Before proceeding, however, a review of the properties of the bridge-balun, or more simply bridge, will assist in describing the circuits to follow.

The Bridge-Balun or Bridge

Fig. 2 is a pictorial outline of the bridge which is used in a number of places in the quadruplexer circuits. The bridge is essentially a 4-terminal hybrid and may take on any one of a variety of forms. The form shown, however, is particularly adapted to high power-television usage.

Referring to Fig. 2, and assuming the the output terminals to be terminated in loads of equal impedance, the application of a voltage at the end input will result in equal and out-of-phase load currents. No signal will appear at the side input. Similarly, a voltage applied at the side input will result in equal and in-phase load currents, and no signal at the end terminal. Voltages may be applied at both end and side inputs simultaneously, resulting in a vector addition of currents in one load and a vector subtraction of currents in the other load. At the same time, each input will be "blind" to the other input, and in the ideal case there is infinite isolation between inputs.

The bridge can operate also in reverse. Equal out-of-phase voltages applied at the output terminals will result in current flow only through a load connected at the end terminal, while equal in-phase voltage applied at the output terminals will result in a current flow only through a load connected to the side terminal.

The foregoing remarks, except those in the paragraph immediately preceding, apply when the output terminals are terminated in identical loads. Another case of special interest arises when the output terminals are terminated in transmission lines, differing in length by 90 electrical degrees, which are in turn terminated in loads of identical impedance. In this instance, when the loads are chosen so as to equal the characteristic impedance of the transmission lines, behavior of the bridge is as noted in the foregoing, except that due to the additional transmission line length in one load branch, the load currents are equal but in phase quadrature. This will be the case for input signals fed into either the end or side terminals. If the two loads remain identical, but do not equal the transmission line characteristic impedance, the equal amplitude and quadrature relation of load currents no longer

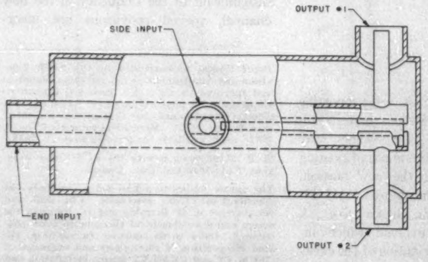

Fig. 2. Bridge-balun

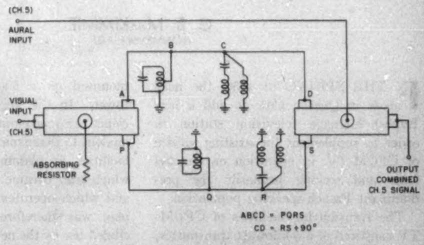

Fig. 3. Notch diplexer schematic

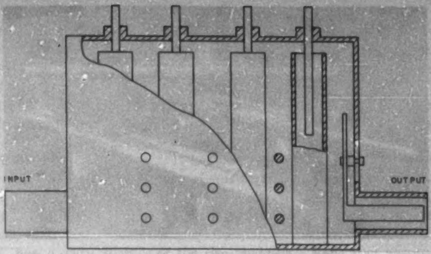
Fig. 4. Combining unit

Fig. 6 (right). Four-stub bandpass filter



holds, and in addition, the two inputs do not remain perfectly isolated. If, however, when feeding a signal to the end terminal, a properly selected load impedance is connected to the side terminal, it is possible to restore the original load current conditions. In addition, the input impedance at the end terminal will have the same value as for the condition of matched transmission lines. Upon close examination of this property of the bridge, one finds that the reflected signals returned along the transmission lines from the mismatched loads appear at the bridge output terminals in-phase, and accordingly feed the side terminal where they may, if desired, be absorbed. These same desirable results could be achieved while feeding the side input, if an absorbing load were connected at the end input.

Advantage is taken of these bridge properties to give the following important features:

1. To provide a constant resistive termination at filter inputs over stop-bands as well as over pass-bands.

2. To provide absorption of the channel five antenna reflection which, if radiated, would result in an objectionable ghost.

The internal construction of the bridge is so arranged, and dimensions are chosen so that 51.5-ohm terminations at the two output terminals result in input impedances at either end or side input terminals of 51.5 ohms over a limited band of frequencies. A particularly broad band input impedance may be obtained at the end terminal by suitable construction of the innermost conductor which may have two or more different diameters throughout its length.

Having summarized the essential characteristics of the bridge element, the first unit of the quadruplexer, the notch diplexer, may now be described.

Notch Diplexer

Combining of the channel five visual and aural signals is accomplished in the notch diplexer. Fig. 3 is a schematic diagram of this unit. All interconnections, including *ABCD* and *PQRS*, actually are made by means of coaxial transmission lines. The reactive elements at *B*, *C*, *Q*, and *R* are connected in shunt across the transmission lines at the points indicated. These elements are shown in the diagram as comprising simple inductive and capacitive components. Actually, they take the form of coaxial stub assemblies having properties similar to those indicated in the schematic representation. The reactive element at *C* consists of a simple series tuned circuit, sharply resonant at aural carrier frequency. The resulting capacitive reactance at the lower frequency of the visual carrier is antiresonated by means of the separate shunt inductor. The reactance element at *R* is identical with that at *C*.

At *B* and *Q*, identical circuits, tuned to antiresonance at visual carrier frequency are used.

The aural signal is delivered to the side terminal of the output bridge, resulting in equal in-phase voltages at *D* and *S*. As the signals proceed to the left, however, the shunt reactance elements at *C* and *R* are encountered. Since these are short circuits for the aural carrier frequency, reflected signals of 100% amplitude are returned towards the right, and to bridge terminals *D* and *S*. Because the electrical distance *DC* is 90 degrees longer than SR, the signals returning at *D* and *S* are now out-of-phase, and therefore appear at the output end terminal of the right hand bridge as desired. If the short circuits at *C* and *R* are not quite perfect, a small portion of the aural signal will continue

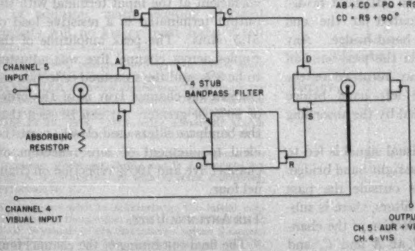


Fig. 5. Combining unit schematic

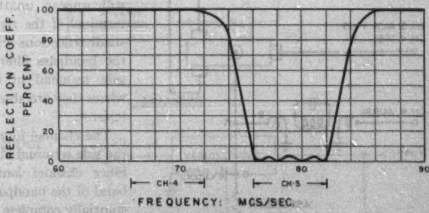

Fig. 7. Input reflection coefficient versus frequency for single 4-stub bandpass filter

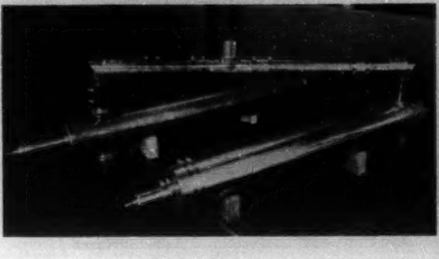

Fig. 8. Antenna unit

Fig. 10. Bridge

towards the left, and result in equal in-phase voltages at A and P. These voltages in turn direct a signal to the side terminal of the input bridge, where an absorbing resistor is used. No aural signal can occur at the end terminal of the left hand bridge.

The visual signal is delivered to the end input of the left hand bridge, so that equal out-of-phase voltages appear at A and P. At visual carrier frequency, all reactance elements are antiresonant, and therefore have no shunting effect. Equal and out-of-phase voltages therefore appear at D and S, causing the visual signal to be delivered to the end terminal of the right hand bridge as desired.

It is necessary, of course, that the diplexer pass without attenuation frequencies other than the visual carrier alone. It can be shown that the power lost in transmission of signals near visual carrier is equal to the square of the reflection coefficient on lines AB and PQ. Also, any such reflected energy will be absorbed in the absorbing resistor, and will not appear at the visual input terminal. The function of antiresonant reactive elements at B and Q is to reduce the reflection coefficient on lines AB and PQ in the portion of the visual spectrum above the color subcarrier. The spacing BC and slope of the susceptance characteristic of the element connected at B is chosen for maximum improvement. The over-all response characteristic is thus made flat within a few tenths of a decibel from 1 mc below to 4 mc above visual carrier frequency, and down less than 1 decibel at 4.2 mc above visual carrier frequency.

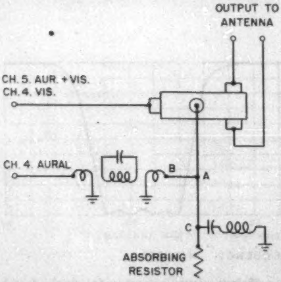

Fig. 9. Antenna unit schematic

Additionally, the notch diplexer circuit establishes a constant input termination at the visual input for signals of all relevant frequencies, regardless of whether or not attenuation takes place within the diplexer.

The Combining Unit

The channel four visual signal is added to the complete channel five signal in the combining unit; see Fig. 4. Referring to Fig. 5, it will be seen that the circuitry resembles very closely that of the notch diplexer. The principle difference is in the nature of the elements inserted in the transmission lines interconnecting the bridges. The two identical bandpass filters, BC and QR, are designed to have a flat response and very small reflection coefficient at their inputs over all frequencies of channel five. Therefore, because of the symmetrical nature of the circuit, it is evident that the complete channel five signal applied at the end terminal of the left hand bridge will appear unattenuated at the end terminal of the right hand bridge. Any small reflections within the pass band of the bandpass filters are returned to the side terminal of the left hand bridge where they are absorbed by the absorbing resistor.

The channel four visual signal is fed to the side terminal of the right hand bridge. Since channel four is outside the pass band of the bandpass filters, there is substantially complete reflection of the channel four visual signal at R and C, and therefore this signal is delivered with little attenuation to the end terminal of the right hand bridge along with the complete channel five signal. Small amounts of the channel four signal which may leak past the bandpass filters are absorbed by the absorbing resistor, but do not arrive at the channel five input terminal. Special measures were taken at the channel four visual input terminal of the combining unit to provide a broad band impedance match.

This input normally tends to be restricted in bandwidth because of the use of a side input of a bridge, and also because the electrical difference in the lengths CD and RS cannot remain exactly 90 degrees for all frequencies occupied by the visual signal. This difficulty was successfully overcome, however, by the use of a carefully designed half-wave broadbanding transformer in series with the channel four visual input.

Fig. 6 is a pictorial sketch of the bandpass filters used in the combining unit. These filters consist of four resonant stubs, mutually coupled together, and inductively coupled to input and output terminals. Re-entrant rods are used for tuning, and the mutual couplings are determined by proper spacing of the individual stubs, and by the use of an appropriate number of rods between the stubs. Fig. 7 is a plot of the reflection coefficient at the input terminal with the output terminated in a resistive load of 51.5 ohms. The peak amplitude of the ripples across channel five was adjusted to be 3%, and the measured reflection coefficient on channel four is of the order of 99% or greater. It can be seen that the bandpass filters used closely meet the ideal requirement of zero reflection on channel five and 100% reflection on channel four.

The Antenna Unit

The final combining of the channel four aural signal with all other signals takes place in the antenna unit in Fig. 8, and shown schematically in Fig. 9. The end terminal of a bridge, Fig. 10, is fed with all signals previously combined in the notch diplexer and combining unit, and these signals therefore appear out-of-phase at the bridge output terminals. The channel four aural signal is brought through a series connected resonant stub assembly, designed to pass only a small band of frequencies centered about the aural carrier frequency, to junction point *A*, and thence to the side input of the bridge. This signal will therefore split into two equal in-phase components at the bridge output terminals. From junction *A*, a separate transmission line leads to an absorbing resistor, and at point *C*, a shunt connected resonant stub, tuned to channel four aural carrier frequency, is connected across the line. Length *AC* is made one quarter wave long in order that the channel four aural signal will see infinite impedance looking towards the absorbing resistor, and will deliver its entire power to the bridge.

As has been previously mentioned the antenna has a significant reflection on channel five. The returning reflected signals arrive at the bridge output terminals in-phase, and therefore appear at the side input of the bridge, where they are directed towards the absorbing resistor. Length *AB* is chosen so that a channel five signal looking from *A* towards *B* sees an infinite impedance, and since the stub connected at *C* has a very high reactance at channel five frequencies, substantially all the channel five energy reflected from the antenna is absorbed, and therefore radiation of a ghost signal is effectively prevented.

Conclusions

It has been established through the successful application of the quadruplexer described herein, that simultaneous operation of two television transmitting stations of medium power into a common antenna and feed system is practical. In the case of CFCM-TV and CKMI-TV substantial savings resulted from the use of the quadruplexer, rather than separate antenna systems.

It has been further shown that, in the case of quadrature fed antenna systems employing dual transmission line feeders, the antenna impedance match need meet usually accepted standards on only one of the two channels. Reflection absorption within the quadruplexer effectively prevents radiation of a ghost signal on the second channel.

While extensive use in television broadcasting of filter systems employing principles similar to those of the quadruplexer described is not envisaged at the present time, it is likely nevertheless that such systems may prove distinctively advantageous and worthy of careful consideration in certain specific cases.

A Transistorized Compandor

THE APPLICATION of multiple-channel communication circuits as provided by carrier and microwave radio systems has been steadily increasing in recent years in the attempt to satisfy the widespread consumer demands, public, private, and military included, for more and better telecommunication facilities. The use of these systems has solved many problems of expansion; however, in turn, the systems have introduced their own problems, in particular the increased susceptibility to interference, crosstalk, and noise as compared to physical voice frequency circuits.

In addition, many existing physical circuits will no longer meet today's toll transmission standards for crosstalk and noise due to processes of a slow, deteriorating nature. The addition of individual compandors to such circuits, either physical or carrier-derived, can in many cases prove economically feasible as a method of improving these facilities to a suitable quality.

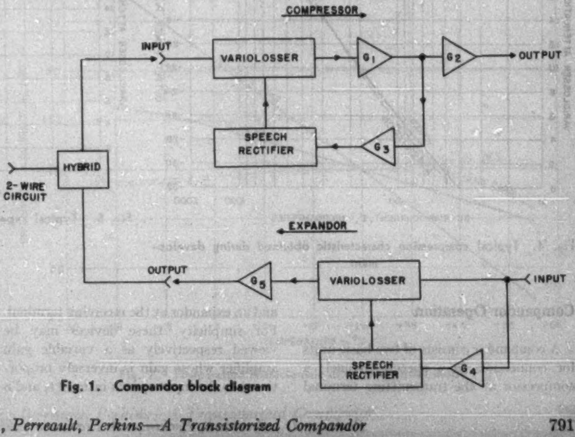

Fig. 1. Compandor block diagram

The principle of companding (compressing and subsequent expanding of the dynamic speech range) has been in use for many years by the telephone industry as a method of improving the transmission quality of communication circuits;[1,2] however, only in recent years has attention been given to the design of versatile, self-contained compandors which can be adapted to a wide variety of application.[3]

This paper describes the design of the Stromberg-Carlson type *545* compandor for general use in voice transmission communication circuits.

Paper 58-906, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 19, 1958; made available for printing May 5, 1958.

J. C. PERKINS, JR., is with the Stromberg-Carlson Company, Rochester, N. Y.; and D. A. PERREAULT and A. F. PERKINS are with O'Hara Associates, Syracuse, N. Y.

The authors wish to acknowledge the initial contributions to this project given by J. L. Wheeler and T. F. Bryzinski of the Stromberg-Carlson Research Department, and the assistance of B. R. Stachiewicz, formerly of the Stromberg-Carlson Company, who established the performance objectives and co-ordinated the development program.

Compandor Operation

A compandor consists of two basic units for connection to a speech channel: a compressor at the transmitting terminal and an expandor at the receiving terminal. For simplicity, these devices may be viewed respectively as a variable gain amplifier whose gain is inversely proportional to the input speech intensity, and a variable attenuator whose loss is directly proportional to its input. Thus high-level speech signals receive little gain or loss in passing through both compressor and expandor, while low-level signals are raised in the compressor and subsequently depressed in the expandor to their original

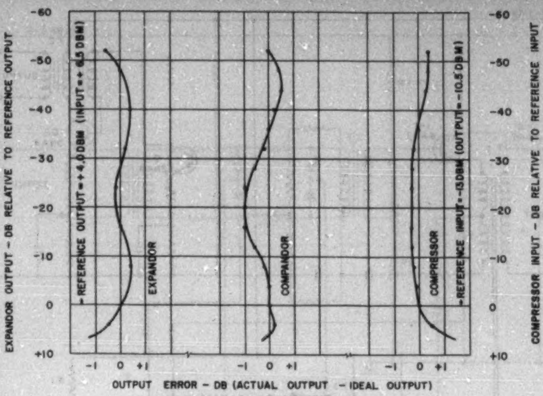

Fig. 6. Tracking characteristic

intensity. This dynamic action of the compandor, when designed to occur at a syllabic rate, will provide a listener with an apparent signal-to-noise improvement in the order of 22 db (decibels) for conventional compandors having compression ratios of 2 to 1. This improvement can vary considerably with speech volume and noise level.[3]

The *545* compandor is of the conventional type: its originality lies in the complete use of transistors as active elements, compact modular construction, and printed circuit techniques.

Design Objectives

In the development of a new product for telephone applications, features which must be considered of primary importance include reliability, power sources, size, installation, and maintenance.

To an industry which is accustomed to measuring performance of a device in terms of 20-year life, the introduction of the transistor will undoubtedly be the main factor in improving the reliability of electronic telephone equipment. The hot cathode vacuum tube, in spite of its extreme versatility and usefulness, is inherently a device of limited life. From all presently available information on transistor life, this limitation does not appear to exist in properly designed semiconductor devices. For this reason it was decided to design the compandor using transistors throughout.

Transistors are also well suited for operation from the standard 48-volt telephone central-office battery. Vacuum tubes usually require a higher voltage supply, which necessitates the additional design of a-c to d-c converters or the installation of a secondary battery supply. The low total power consumption of transistors is still another point in favor of their usage.

Within the past decade, telephone operating companies have been forced to increase their inside plant facilities to keep up with the service demands of expanding population. Thus, physical size is becoming increasingly important in the design of new products. Transistors, in conjunction with miniature components and printed circuit boards, are readily adaptable in providing a compact design.

Maintenance costs consume a large portion of an operating company's budget. Although increasing the reliability of equipment will tend to reduce these costs, it is still necessary to consider the servicing aspects of new designs. For this reason, it was felt that plug-in construction of the compandors was essential to keep the out-of-service time of compandored channels to a minimum.

Electrical Arrangement

In Fig. 1, the electrical arrangement of the compandor is shown in block form. The basic unit is designed for 4-wire operation, although resistance hybrids are included as strapping options where 2-wire operation is required. Input signals to the compressor pass through a variable gain device commonly referred to as the variolosser, are amplified and passed to the line. The variolosser is d-c controlled by a rectified portion of the output speech in a backward-acting circuit, its loss increasing as the intensity of the input signal increases, thus reducing the dynamic range of the output.

In the expandor, compressed signals received from the far terminal are impressed on a variolosser controlled in a forward-acting circuit. As the input increases, the loss is reduced, thus increasing the dynamic range of the output.

The compressor and expandor actions for a single test tone of varying intensity are graphically illustrated in Fig. 2. Although compandors can be applied to a variety of operating levels, the two cases shown are for level points of $-16/+7$ and $-13/+4$ db referred to 1 milliwatt which are most commonly encountered in tele-

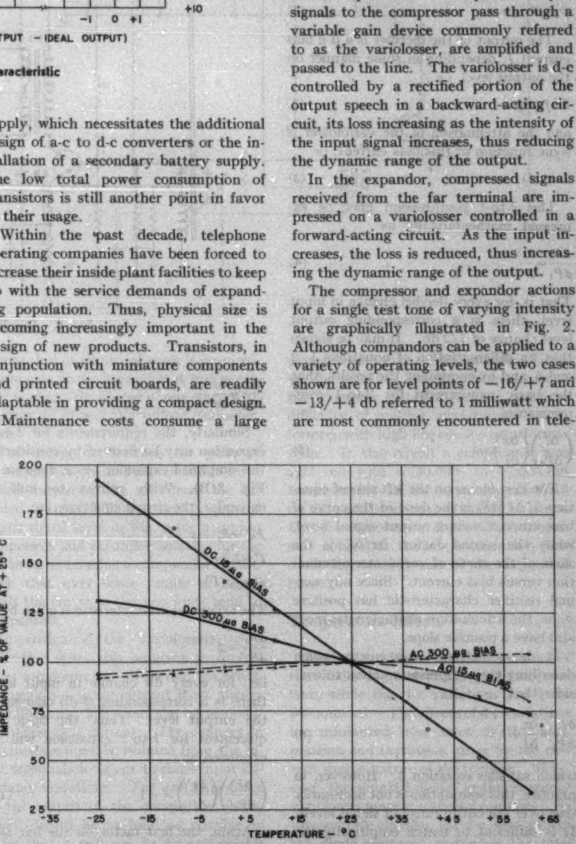

Fig. 7. Temperature characteristic of the variolosser diode

phone offices. It will be noted that the input levels to both compressor and expandor are made identical for both cases by the use of 3-db strap pads. Internal gain controls are then used to provide proper drop levels and to accommodate the required net system gain.

Variolosser Design

To develop the requirements for 2-to-1 compression the more simple compressor block diagram in Fig. 3(A) may be considered, since the amplifier gains are all constant and will not enter into the final result. Expressing the relationship between input power P_i, output power P_0, and attenuation x, in db

$$P_0 = P_i - x \tag{1}$$

The output of the rectifier is a d-c bias current I, depending in some manner on the output level, i.e.,

$$I = f_1(P_0) \tag{2}$$

and the attenuation of the variolosser is some function of this bias current, or

$$x = f_2(I) \tag{3}$$

The 2-to-1 compression may be expressed mathematically as

$$\frac{dP_0}{dP_i} = \frac{1}{2} \tag{4}$$

That is, for every decibel change in input level, there is a corresponding output level change of 1/2 db. It may be shown that by differentiation of equations 1, 2 and 3, and by combining the results, that the basic requirement for 2-to-1 compression is

$$\left(\frac{\partial I}{\partial P_0}\right)\left(\frac{\partial x}{\partial i}\right) = 1 \tag{5}$$

The first factor on the left side of equation 5, $\partial I/\partial P_0$ is the slope of the curve of bias current versus output signal level, while the second factor, $\partial x/\partial I$, is the slope of the curve of variolosser attenuation versus bias current. Since any normal rectifier characteristic has positive slope, the attenuation characteristic must also have a positive slope.

It is sometimes convenient when describing the compression action to consider that

$$\frac{\partial I}{\partial P_0} = \frac{\partial x}{\partial I} = 1 \tag{6}$$

which satisfies equation 5. However, in practice, this assumption is not necessarily true over the entire range of signal levels. It is sufficient to match empirically the slopes of the functions as plotted in Fig. 4, which satisfies equation 5 in the form

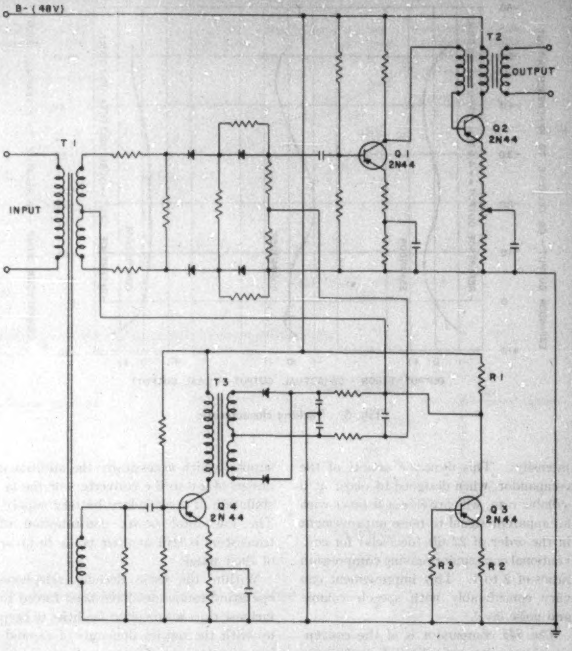

Fig. 8. Simplified expandor schematic

$$\frac{\partial I}{\partial P_0} = \frac{\partial I}{\partial x} \tag{7}$$

Similarly, the requirements for 1-to-2 expansion may be derived by considering the simplified expandor block diagram of Fig. 3(B). With primes to indicate expandor, the circuit equations are

$$P_0' = P_i' - x' \tag{8}$$

$$I' = f_1'(P_i') \tag{9}$$

$$x' = f_2'(I') \tag{10}$$

The expansion characteristic is given by

$$\frac{dP_0'}{dP_i'} = 2 \tag{11}$$

i.e., for every db change in input level there is a corresponding 2-db change in the output level. Thus, the basic requirement for 1-to-2 expansion will be expressed as

$$\left(\frac{\partial I'}{\partial P_i'}\right)\left(\frac{\partial x'}{\partial I'}\right) = -1 \tag{12}$$

Again, the first factor on the left side of equation 12, $\partial I'/\partial P_i'$, is the slope of the curve of bias current versus input signal level while the second factor, $\partial x'/\partial I'$, is the slope of the curve of variolosser attenuation versus rectifier current. This quantity is made negative by means of the variolosser circuit configuration, i.e., the attenuation decreases as the current increases.

The design approach is similar to that for the compressor. The customary plot of the functions is as shown in Fig. 5. By empirically matching the slopes of these curves equation 12 may be satisfied in the form

$$\frac{\partial x'}{\partial I'} = -\frac{\partial P_i'}{\partial I'} \tag{13}$$

In both the compressor and expandor, the desired rectifier characteristic is approached by designing the rectifier as a current source so that the effect of load changes caused by variations in the d-c resistance of the variolosser with current will be minimized. This approach is limited because of the wide range of load variation which the variolosser presents and the relatively small amount of power available at the input to the rectifier.

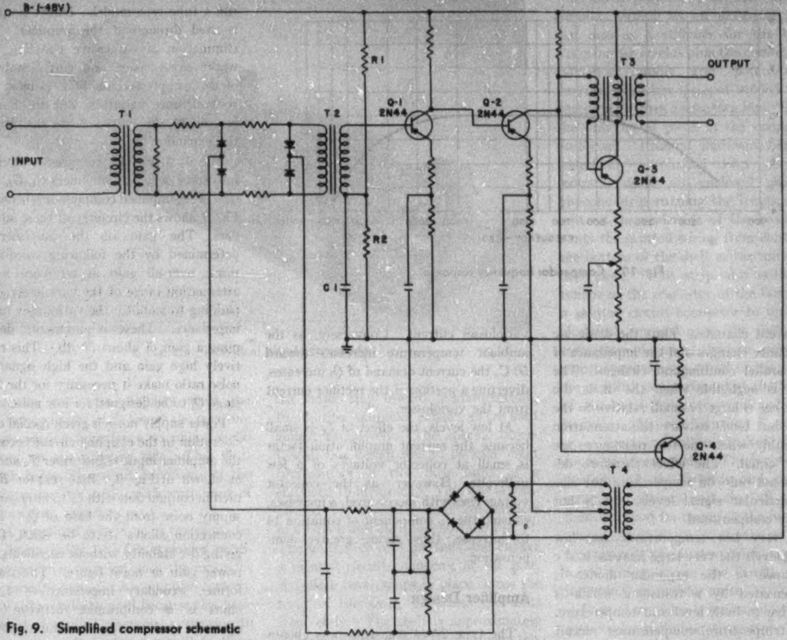

Fig. 9. Simplified compressor schematic

The variolosser is a balanced attenuator whose attenuation depends on the bias current fed to it from the rectifier by means of a simplex-type connection. The positive sloping attenuation function required in the compressor is obtained by using series resistance followed by shunt diodes. The negative slope required in the expandor is obtained by using series diodes followed by shunt resistors.

The approximate diode characteristic appropriate for this type of circuit is generally well known. The exact characteristic was determined in conjunction with diode manufacturers experienced in supplying this type of diode, so as to take advantage of their maximum yield. The diodes are selected on the basis of their dynamic impedance when biased in the forward direction.

With this type of diode, a 2-stage variolosser is required in both the compressor and the expandor in order to obtain the wide range of attenuation required. Exact matching of the characteristics shown in Figs. 4 and 5 is accomplished by adjusting the variolosser and rectifier resistors. Since these circuits are not entirely independent of each other, a great deal of empirical work is required. In the case of the expandor, it was necessary to shunt the diodes of one stage with resistors to obtain the proper characteristics.

The difference between the pairs of curves in Figs. 4 and 5 represents an error in the output of the unit from the expected output. This error is plotted versus signal level in Fig. 6 for a typical compressor and expandor and also for the two in series forming a compandor circuit. Note that over some ranges of signal levels the errors in the two units tend to compensate.

In designing the variolossers, consideration must also be given to several other requirements. To avoid distortion the peak a-c signal current must always be sufficiently less than the corresponding diode bias current. The changes in attenuation must be isolated from the input terminals so as not to cause input impedance variations. The load impedance at the output of the compressor variolosser should be as high as possible in order that it will not be an appreciable shunt on the diodes at the low attenuation (high diode impedance) end of the compression range. The limitations here are the relatively low input impedance of the transistor amplifier and the practical difficulty of making miniaturized transformers with high-impedance transformations. In this circuit a compromise was achieved with a 30,000- to 1,200-ohm transformer. In the expandor the load on the variolosser output should be low so that the diodes can still provide the necessary control at the low attenuation (low diode impedance) end of the expansion range.

Temperature Effects

As shown in Fig. 7, the a-c impedance of the diodes is quite stable with temperature, while the d-c variations are quite pronounced. The effects of d-c variations are minimized over most of the compression and expansion range by the current source nature of the rectifier. However, the shunted diodes in the expandor variolosser present a special problem. As temperature changes, the d-c resistance of the diode changes; and while the total current through the parallel combination remains relatively constant, the division

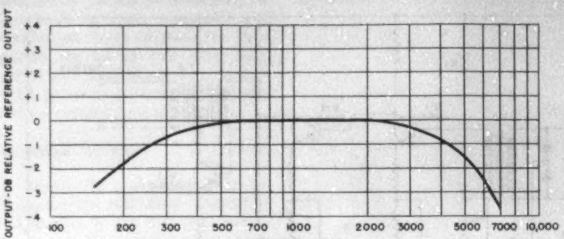

Fig. 10. Compandor frequency response

of current changes. Thus the diode a-c impedance changes and the impedance of the parallel combination changes. The effect is negligible when the diode d-c resistance is large or small relative to the shunt but tends to vary the attenuation noticeably when the two resistances are about equal. The effect therefore depends not only on temperature but also on particular signal levels and is not readily compensated.

At very low temperatures and low signal levels the very large increase in d-c resistance of the expandor diodes is compensated by a transistor which is sensitive to both level and temperature. The temperature compensating circuit comprises Q_3, R_1, R_2, and R_3 of Fig. 8. The circuit controls the direction and magnitude of current flow between the collector of Q_3 and the variolosser as a function of temperature, primarily, and with level as a secondary effect. The current flowing in R_1 is determined by $B-$ since the collector is close to ground. The current required by Q_3 is determined by the following well-known equations:

$$I_C=\alpha I_E+Ico \qquad (14)$$

$$I_E=E_B/R_2 \qquad (15)$$

$$E_B=Ico(R_3) \qquad (16)$$

Since *Ico* is a function of temperature, I_c is temperature dependent, and its shape is determined by the values of α, *Ico*, R_2, and R_3.

The values of R_1, R_2, and R_3 are so chosen that the collector current required at 25 C (degrees centigrade) is approximately equal to the current supplied from $B-$ through R_1. At this temperature there is no current flow between Q_3 and the variolosser. The entire variolosser current is supplied by the rectifier. As the ambient temperature approaches zero C, the current demand of Q_3 decreases, thus allowing a portion of the current through R_1 to supplement the variolosser current. Conversely, as the ambient temperature increases toward 50 C, the current demand of Q_3 increases, diverting a portion of the rectifier current from the variolosser.

At low levels, the effect of I_E is small because the current amplification factor is small at collector voltages of a few millivolts. However, as the collector voltage rises with speech level, α increases, causing the I_E component of equation 14 to increase, thus giving greater compensation.

Amplifier Design

The type *2N44* transistor was chosen as a medium beta relatively high peak inverse voltage unit, allowing economical use of the $B-$ supply. Solid tantalum capacitors are used in the amplifiers because they are inherently stable with temperature, they are considered to have long life, and they are small in size.

The power drain of the compandor has been kept to a minimum consistent with stability and reliability. The unit draws 30 milliamperes at 48 volts or about 1.5 watts of power. This is compared to about a 4.5-watt filament power alone to run a tube-type model. Direct coupling is used throughout the amplifier. The elimination of capacitive coupling networks saves space and cost. Stability of the compressor amplifier is most important since variations due to changes in gain of the amplifier are doubled in the expandor.

Fig. 1 shows the compressor divided into three separate amplifiers G_1, G_2, and G_3. The simplified compressor schematic, Fig. 9, shows the circuitry of these amplifiers. The gain of the amplifier is determined by the following considerations: over-all gain at reference level, attenuation range of the variolosser, and padding to stabilize the variolosser input impedance. These requirements determine a gain of about 50 db. This relatively high gain and the high signal-to-noise ratio make it necessary for the first stage Q_1 to be designed for low noise.

Power supply noise is given special consideration in the coupling circuit between the amplifier input transformer T_2 and Q_1 as shown in Fig. 9. Bias resistor R_1 is used in conjunction with C_1 to filter power supply noise from the base of Q_1. This connection allows R_2 to be small, thus giving d-c stability without sacrificing a-c power gain or noise figure. The transformer secondary impedance of 1,200 ohms is a compromise between the optimum values for maximum power transfer and low noise figures.

Isolation between the rectifier and the signal output is provided by the rectifier amplifier Q_4, and the output amplifier Q_5. The rectifier amplifier is required because the *2N44* transistor is not capable of supplying sufficient power for both the line and the rectifier over the required temperature range.

The change in output impedance of the amplifier with variations in transistor parameters presents an additional problem. The unbypassed emitter resistor is

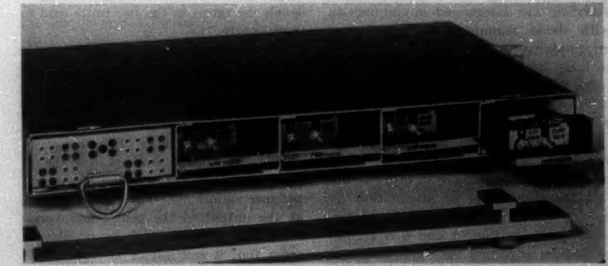

Fig. 11. Compandor shelf mounting four compandors and junction box

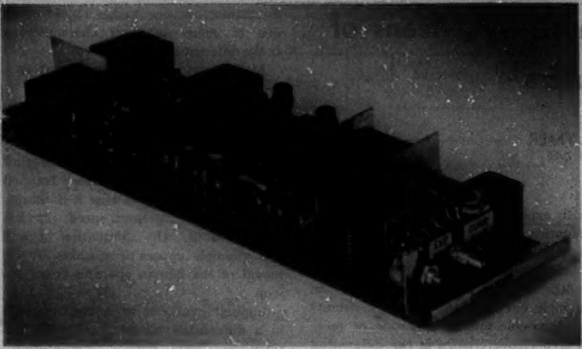

Fig. 12. Individual plug-in compandor

high to give gain stability while the tertiary winding of T_3 lowers the resulting high output impedance to about 4,000 ohms on the primary side. This feedback holds the output impedance of the compressor to ±5% with variations of transistor parameters.

A simplified schematic of the expandor is shown in Fig. 8. The expandor amplifier design is simpler since the expandor is forward-acting. An amplifier preceding the rectifier is used because this basic design is applied to special systems with lower expandor input levels than those shown in Fig. 2.

For economy of manufacturing, the same rectifier transformer and output transformer are used in both compresser and expandor. A full-wave bridge is used in the compressor where the maximum d-c resistance of the load on the rectifier is greatest because no shunts are used on the variolosser diodes. The extra diodes are relatively inexpensive and are in fact of the same type used in the variolosser, without special selection.

Fig. 10 shows the compandor frequency response.

Mechanical Design

The compandor is a modular, printed circuit design. The use of transistors was the major step toward miniaturization. In addition, tantalum capacitors are used almost exclusively. The specific objective in this design was to package eight compandors in two rack units of a standard 19-inch rack. This was accomplished by mounting four compandors in a 1-rack unit shelf, as shown in Fig. 11. The units slide into the shelf and engage a printed circuit connector at the rear. A 1-piece cover snaps in place across the front of the shelf to enclose the units completely. The shelf is approximately 10 inches deep and extends approximately 6 inches beyond the front face of the mounting rack.

To increase the volumetric efficiency and still maintain simplicity and accessibility, modular assembly of the smaller components was adopted. The modules and larger components such as transformers are mounted on the main printed circuit board. The "decks" of the modules are also printed circuits. In general, the modules represent logical circuit groupings; variolosser, amplifier, etc. Since the compandor is made up of two completely separate circuits, each with wide ranges of signal levels, careful attention was given to the physical layout. The compressor is located along the right side of the unit, as shown in Fig. 12, and the expandor along the left side.

A metal partition separates the two circuits, serving as an electrical shield and also as a stiffener for the board. Transformer shields plus the combination extractor handle and potentiometer mounting bracket are spot-welded to the partition to form a subassembly. This is the only metal piece in the compandor unit itself. Framing hardware has been completely eliminated since the unit mounts inside an enclosed shelf. A phenolic strip running the length of the unit on the underside of the board prevents the printed wiring from contacting the bottom of the shelf as the unit is slid into place. This strip also guides the tongue at the rear edge of the board into a printed circuit connector to make the electrical connections to the shelf. The connectors of each of the four compandor compartments were wired to the connector of a fifth compartment at the left side of the shelf by a conventional wiring harness. This compartment is occupied by a "junction box" to which all external connections are made. The junction box contains all the hybrids and pads for strapping options and also all the tip jacks required for metering the input and output levels of the compandors. This arrangement eliminates much back-and-forth wiring across the length of the individual compandor units.

Ease of servicing is increased by use of sockets for mounting transistors and by the special manner in which the modules are connected to the printed board. The bus wire studs of each module are dip-soldered to terminals swaged to the circuit side of the main board, rather than soldered to the printed wiring itself, in order that replacement may be accomplished without damage to the printed board.

Direct System Synthesis by Means of Computers

A. BEN CLYMER
NONMEMBER AIEE

BEFORE a system can be simulated on an operational analog computer, a passive-element analog computer, a digital differential analyzer, or a digital computer, it is necessary to derive or synthesize a set of differential equations which yield the response of the system to an arbitrary excitation. Every constant and function in the differential equations must be known.

For some systems the state of the art permits one to derive theoretically a formula or value for each function and constant. It is then straightforward to simulate such a system on a computer.

Most systems, however, have at least one constant or function which cannot as yet be obtained from theory. For these systems it is necessary to have recourse to experimental determination. If experimental techniques can be devised for the measurement of the "characteristics" (i.e., coefficients, exponents, functions, etc.) which cannot be obtained from theory, then analog simulation of even these systems is straightforward.

The systems which can be treated by the methods considered in this paper are those which do not readily reveal all of their characteristics when investigated by means of both theory and experiment. They are legion.

This paper presents two general methods for using a computer in conjunction with experimental results for the determination of characteristics in the differential equations representing a system. One method, called herein "implicit synthesis," consists of the use of an implicit circuit (i.e., "forcing" circuit) to determine and display one or more desired characteristics in the differential equations for a system, given the rest of the terms in the differential equations, as well as the dynamic response of the system to some arbitrary excitations which exercise the dependent variables over their full ranges. The implicit circuit contains a mechanization of a differential equation which is complete except for the unknown characteristics. The missing characteristics are synthesized by the implicit circuit by continuously comparing the values generated for dependent variables with the experimental time histories of the dependent variables, and greatly amplifying the differences. A more extended explanation of the principle will be offered later.

Implicit synthesis is thus a distinct mode of application of computers. It differs from the usual mode of application, in which one knows the differential equation, including all characteristics, and one knows the excitation, while one wishes to determine the solution to the equation, which is the dependent variable as a function of the independent variable. By contrast, in implicit synthesis one knows the solution and the excitation, but one wishes to determine one or more unknown characteristics in the differential equations.

Much more common at present as a technique than implicit synthesis is manual trial-and-error setting of the potentiometers in an explicit analog circuit in order to match by eye or by minimum error criterion a given time history of a dependent variable. Implicit synthesis is superior because it is characterized by: 1. greater speed, 2. less error, and 3. the elimination of several possible causes of mistakes by removal of the human operator from the loop.

Implicit synthesis of a characteristic in a differential equation is to be distinguished from "implicit computation" of a quantity from an algebraic relationship.[1] A familiar example of an implicit computation is division by means of a multiplier and a high-gain amplifier. In this example, one wishes to find y and $xy=z$, given x and z. It can be done by means of a circuit of the type diagrammed abstractly in Fig. 1.

Extensive inquiry on the part of the author has failed to reveal any significant use of implicit synthesis on general purpose computers. It is apparently a virgin field, so far as most users of computers are concerned. Yet implicit synthesis has an interesting history which dates at the latest from World War I, when the Ford Instrument Company employed this principle in a mechanical analog device for determining the speed and course of a target ship for naval fire control purposes, where the range and bearing to the target were known continuously and one's own ship's speed and course were known. More elaborate applications have since been developed in the field of fire control engineering, and in other branches of the special-purpose computer field as well.

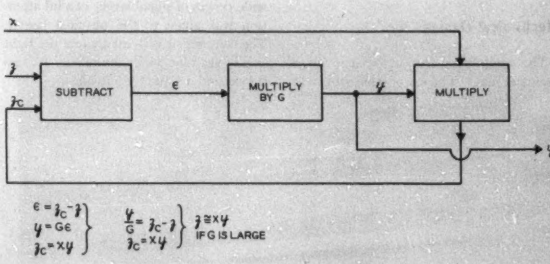

Fig. 1. Division by implicit computation

Paper 58-1003, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Pacific General Meeting, Sacramento, Calif., August 19–22, 1958. Manuscript submitted May 8, 1958; made available for printing June 11, 1958.

For the analog computer findings reported herein and for valuable suggestions concerning the design of circuits for implicit synthesis, the author is indebted to Arnold M. Bartz of Dow Chemical Company, Midland, Mich., formerly with North American Aviation, Inc.; John J. Nichol, James C. Italiano, Raymond M. Kisner, and Charles R. Walli, of the Columbus Division of North American Aviation, Inc., Columbus, Ohio. Burt Went, also of the Columbus Division, conducted the digital computer studies. The author acknowledges also the many ideas derived from conversations with Vernon Larrowe of the Willow Run Research Laboratory of the University of Michigan, Ypsilanti, Mich.; David Sparks of Tammen and Denison, Chicago, Ill.; Howard Hamer and Jerome Kennedy of Electronic Associates, Inc., Long Branch, N. J., and Chicago, Ill., respectively; and others.

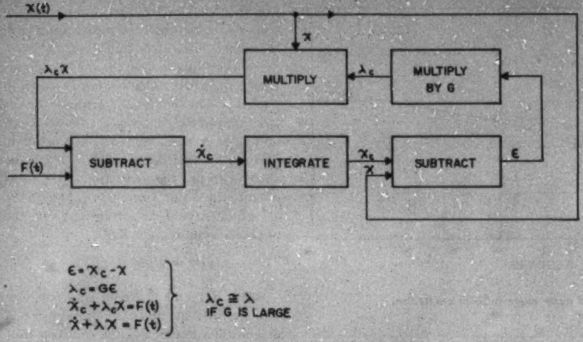

Fig. 2. Implicit synthesis of first-order system

Implicit Synthesis

Implicit Synthesis of First-Order System

If one has a differential equation, say, $\dot{x}+\lambda x=F(t)$, in which one knows $x(t)$ and $F(t)$ but wishes to determine λ, the implicit computation is called herein "implicit synthesis of the characteristic λ." An abstract diagram of a circuit for this purpose is given in Fig. 2. This is a simple case of implicit synthesis; accordingly, the circuit will be explained.

In Fig. 2, $x(t)$ and $F(t)$ are given functions of time, and λ_c is the answer computed by the circuit. Consider the consequences if λ_c were not very nearly correct: $\lambda_c x$ would be wrong, and hence so would $\dot{x}_c$, which would make x_c start to vary away from its nearly correct value, thus making ϵ vary, and this in turn would change λ_c. If the algebraic signs in the circuit are properly designed, λ_c will be driven by the forcing circuit to very nearly its correct value, in principle. If $F(t)$ comes to a constant steady-state value, λ_c will become constant at very nearly its correct value and x_c will very nearly equal x. Even if $F(t)$ varies, the circuit will strive to maintain λ_c at very nearly its correct value at all times. The larger the value of the gain G, the smaller the error in λ_c, provided that the circuit remains stable.

Of course, no one would trouble to use a computer to determine λ in this case, since it would be so simple to calculate or to measure on the actual system a static x under a steady F and calculate λ as F/x. Nevertheless, the circuit will be discussed here in some detail, since it embodies many of the principles which are involved in determining system characteristics in complicated sets of nonlinear differential equations which do not lend themselves readily to experimental determination on the actual system.

One may analyze the behavior of the circuit shown in Fig. 2 by manipulation of the equations which represent the circuit and the physical system:

$$\epsilon=x_c-x \tag{1}$$

$$\lambda_c=G\epsilon \tag{2}$$

$$\dot{x}_c+\lambda_c x=F(t) \tag{3}$$

$$\dot{x}+\lambda x=F(t) \tag{4}$$

where

ϵ = error in x_c
x_c = computed value of x at any instant
x = actual response of the first-order system
G = large number (gain)
λ_c = computed value of λ at any instant
λ = unknown characteristic of the first-order system
$F(t)$ = excitation of the first-order system

First, ϵ can be eliminated between equations 1 and 2:

$$G^{-1}\lambda_c=x_c-x$$

$$\text{or}\quad x_c=x+G^{-1}\lambda_c \tag{5}$$

Next, x_c can be eliminated between equations 3 and 5:

$$\dot{x}+G^{-1}\dot{\lambda}_c+\lambda_c x=F(t) \tag{6}$$

Finally, $F(t)$ can be eliminated between equations 4 and 6:

$$G^{-1}\dot{\lambda}_c+x\lambda_c=\lambda x \tag{7}$$

If x is constant, the circuit may be seen to have a damped exponential transient whose time constant is $(Gx)^{-1}$, i.e., the higher the gain or the larger the response x, the more rapidly the circuit attains the desired answer. On the other hand, the lower the gain or the smaller the value of x, the more sluggishly λ_c approaches λ.

It is to be noted that the circuit goes unstable when x goes negative. To prevent this, it is necessary to include in the circuit a device which maintains at all times a set of algebraic signs which keeps the system stable, regardless of the sign of x. This can be accomplished by means of an absolute magnitude circuit inserted either in the λ_c line or in the x line to the multiplier.

The first alternative is used in the analog circuit shown in Fig. 3, which is one possible way to render the abstract circuit in Fig. 2 with operational analog components. Two slight refinements will improve the performance of this circuit. One is to put a capacitor (about 1,000 micromicrofarads) around the high-gain amplifier as a filter and also to reduce the steady-state error. Another is to bias out any unbalance voltage

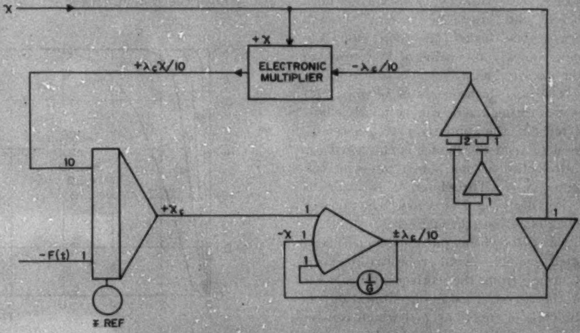

Fig. 3. Analog circuit for implicit synthesis

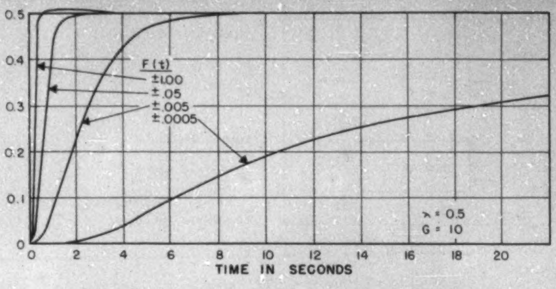

Fig. 4. Dependence of circuit speed upon magnitude of excitation

arising from the diodes by means of a potentiometer fed by reference voltage, in order to insure that the voltage $-\lambda_c/10$ never changes sign, especially for small values of input.

The implicit synthesis circuit shown in Fig. 3, when set up on an Electronic Associates analog computer, did an excellent job of determining λ, provided that x stayed away from a narrow band of values around zero. For example, Fig. 4 shows the behavior of λ_c when x is constant. It is evident that λ_c always approaches the correct value λ with a speed which is greater for larger values of $F(t)$. However, there is a steady-state error which varies inversely with $F(t)$. The error is eliminated if a filter capacitor is used around the high-gain amplifier, because the capacitor introduces an integration. Fig. 5 shows that higher loop gain in the implicit synthesis loop does increase the speed with which the answer is approached, as derived by the foregoing analysis. If $F(t)$ passes through zero, the circuit momentarily generates a wrong answer, as shown in Fig. 6 (A). However, λ_c is correct both before and after the passage through zero. The higher the loop gain, the more quickly the value of λ_c returns to the correct value λ.

The pip which occurs in λ_c when $F(t)$ passes through zero can be nearly eliminated if the potentiometer normally used to trim the diodes is employed for introduction of one's best guess of the value of λ. The closer λ_c is made to λ initially, the less wrong the answer when $F(t)$ passes through zero.

An $F(t)$ which passes through zero often enough could conceivably keep λ_c away from the correct value λ all of the time. This is one limitation on the class of functions $F(t)$ which can be used in conjunction with this circuit for implicit synthesis of the characteristic λ of a first-order system. An allowable sinusoidal $F(t)$ is shown in Fig. 6 (B).

If the true λ of the system is suspected of being a function of x rather than constant, this can be tested by plotting λ_c against x instead of against time. If the resulting curve is a horizontal straight line, except for noise and erratic displacements due to shortcomings of the signals and of the implicit synthesis circuit, then λ is a constant. On the other hand, if $\lambda_c(x)$ retraces itself over some curve other than a horizontal straight line, as x varies, then λ has been shown to be the function of x which the computer has plotted as $\lambda_c(x)$. Thus, implicit synthesis can yield nonlinear characteristics as well as constant coefficients.

The accuracy of implicit synthesis of λ for a first-order system, with the use of the analog circuit just discussed with a gain of at least 100, is usually excellent, the error being less than 1%. Additional error could be introduced by the transducers or magnetic tapes which convey $x(t)$ and $F(t)$ to the computer from the test setup of the system. If the system is not in fact exactly first-order, then of course a first-order representation will be still less accurate.

Another approach with which to determine λ for a first-order system is shown in Fig. 7. The circuit determines λx as the amplified difference between x_c and x, and then employs an open-loop division by x to determine λ. It can be shown from the equations for this circuit that the time constant of the λ_c exponential-decay transient in the implicit circuit is given by

$$\tau = (G + \dot{x}/x)^{-1} \tag{8}$$

Clearly, if $\dot{x}$ and x are of opposite sign at some instant, and if their ratio has a magnitude exceeding G, the time constant can go negative. This means that under some conditions the implicit circuit can go unstable. This defect of the circuit makes it unsuitable for some class of functions $F(t)$, just as was the case with the circuit previously discussed.

A further minor difficulty is experienced if the divider is so designed that it must be fed a positive divisor. This would require an absolute magnitude circuit. Also, since "λ_c" changes sign, if x changes sign, either the dividend or the quotient must pass through an absolute magnitude circuit in order to keep the answer of constant algebraic sign.

If λx is plotted against x, one may see whether this function is nonlinear. If it is, usually one can dispense with the divider and its associated absolute magnitude circuits, since then λx is the quantity which is of direct interest. However, one may plot λx from the previous circuit also, so this is no advantage for either circuit.

Preliminary tests indicated no great differences between the performances of the two circuits under most condi-

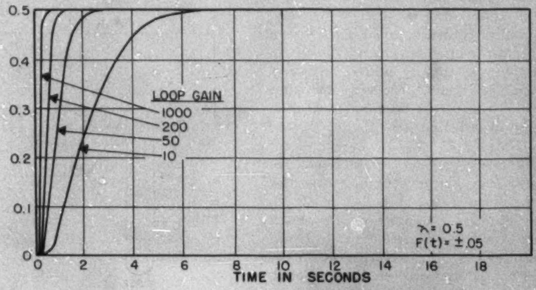

Fig. 5. Dependence of circuit speed upon implicit loop gain

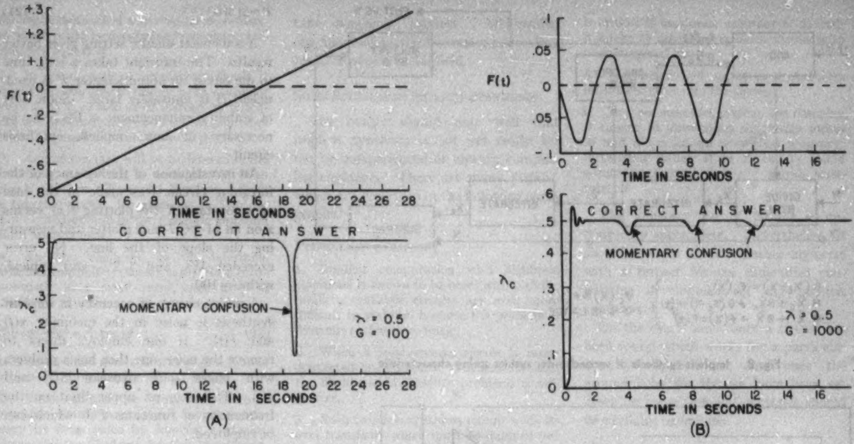

Fig. 6. Two examples of momentary confusion of circuit after crossing zero

tions. The two circuits can be contrasted on the basis of what is in the implicit loop. In one case the implicit loop is chiefly a differentiator, and various operations are then performed open-loop on the result. In the other case the inverses of these operations are performed inside the loop, and the loop yields the answers directly. Any implicit synthesis circuit may be rendered in either of these extreme forms or any form in between (some operations being inside the loop and others open-loop). In some applications it may be desirable to provide automatic loop gain control.

It might be possible to improve the stability of the foregoing circuit by changing the high-gain amplifier to an integrator with large input gains and by feeding the output back to the input through a potentiometer. This modified implicit synthesis circuit would have a second-order instead of a first-order transient. Hence the transient could be damped out quickly by proper setting of the potentiometer, which introduces artificial damping. A corresponding change could be made in the "circuit" if implicit synthesis were conducted on a digital computer or digital differential analyzer.

IMPLICIT SYNTHESIS OF A SECOND-ORDER SYSTEM

Consider next a system of second order of the form

$$M\ddot{x}+B\dot{x}+Kx=F(t) \tag{9}$$

A typical problem for implicit synthesis would be to determine K, knowing M, B, $x(t)$, and $F(t)$.

One approach would be analogous to that used in the foregoing for finding λ for a first-order system, namely, to let the unknown characteristic K be the quantity obtained by amplifying the difference between $x(t)$ and the implicitly synthesized quantity $x_c(t)$. However, it will be more instructive to discuss another approach, which was also applied in the foregoing to a first-order system.

Let the quantity $G(x_c-x)$ represent $Kx=f(x)$ instead of only K. Then this Kx can be plotted against x and the slope can be read off. In fact, if K depends upon x, the function $f(x)$ will be displayed directly as the ordinate of the plot. An abstract circuit for this purpose is given in Fig. 8, and a satisfactory operational analog circuit for implicit synthesis of $f(x)$ is given in Fig. 9. It is to be noted that the circuit in Fig. 9 for a second-order system takes less equipment than the circuit in Fig. 3 for a first-order system.

The circuit in Fig. 9 is easy to analyze in its essential respects. One obtains the following equations:

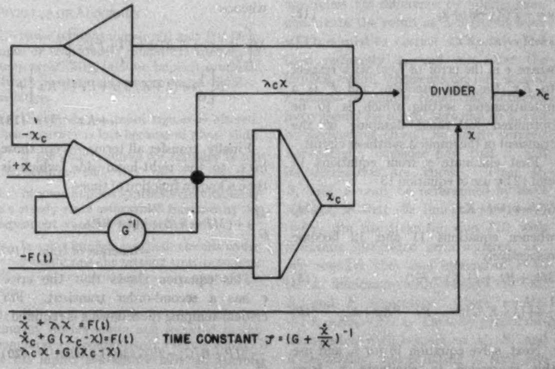

Fig. 7. Alternative analog circuit for implicit synthesis

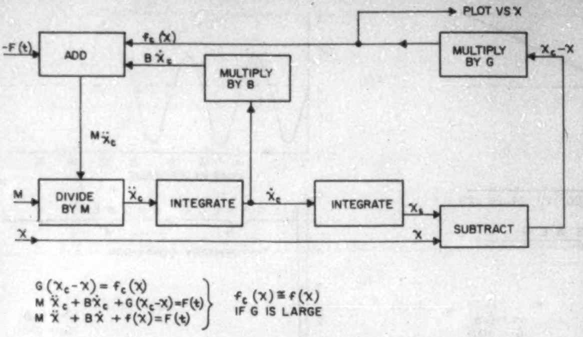

Fig. 8. Implicit synthesis of second-order system spring characteristic

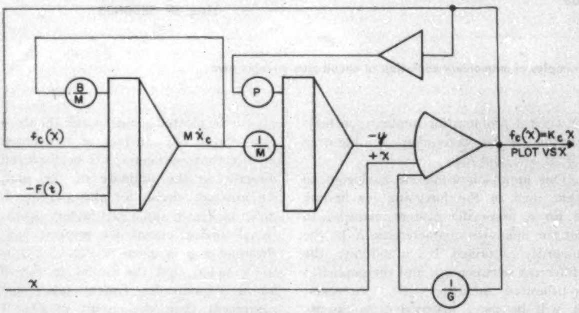

Fig. 9. Analog circuit for finding spring characteristics of second-order system

$$M\ddot{x}+B\dot{x}+Kx=F(t) \tag{10}$$

$$M\ddot{x}_c+B\dot{x}_c+G(y-x)=F(t) \tag{11}$$

$$\dot{y}=-PG(y-x)+\dot{x}_c \tag{12}$$

$$\epsilon=G(y-x)-Kx \tag{13}$$

where ϵ is the error of $f_c(x)$ with respect to Kx, the true function, and P is a potentiometer setting which is to be optimized for rapid damping of the transient of the implicit synthesis circuit.

First eliminate y from equations 11 and 12 by use of equation 13:

$$G(y-x)=\epsilon+Kx \tag{14}$$

whence equations 11 and 12 become respectively

$$M\ddot{x}_c+B\dot{x}_c+\epsilon+Kx=F(t) \tag{15}$$

$$\frac{1}{G}\dot{\epsilon}+(1+K/G)\dot{x}=-P\epsilon-PKx+\dot{x}_c \tag{16}$$

Next, solve equation 16 for $\dot{x}_c$ and use this expression to eliminate x_c from equation 15:

$$\dot{x}_c=\frac{1}{G}\dot{\epsilon}+(1+K/G)\dot{x}+P\epsilon+PKx \tag{17}$$

whence

$$M\left[\frac{1}{G}\ddot{\epsilon}+(1+K/G)\ddot{x}+P\dot{\epsilon}+PK\dot{x}\right]+ B\left[\frac{1}{G}\dot{\epsilon}+(1+K/G)\dot{x}+P\epsilon+PKx\right]+ \epsilon+Kx=F(t) \tag{18}$$

Finally, transfer all terms, except those in ϵ, to the right-hand side, which is then a known function of time:

$$\frac{M}{G}\ddot{\epsilon}+(MP+B/G)\dot{\epsilon}+(1+BP)\epsilon =\text{function of time} \tag{19}$$

This equation shows that the error ϵ has a second-order transient. For critical damping the following is required:

$$\frac{G}{M}(MP+B/G)=2[(G/M)(1+BP)]^{1/2} \tag{20}$$

whence

$$P\approx 2(MG)^{-1/2} \tag{21}$$

A somewhat smaller setting gives better results. The transient takes a long time to die out if no potentiometer P is used, unless B is unusually large. Some sort of stability enhancement is likely to be necessary in any implicit synthesis circuit.

An investigation of the accuracy of the foregoing circuit was made in the case of a constant K by plotting $f(x)$ versus x on an 11- ×17-inch plotter and measuring the slope of the line. No error exceeded 1%, and 1/2% was typical, with $G=100$.

A major enemy of accuracy in implicit synthesis is noise in the incoming $x(t)$ and $F(t)$. If one employs filters to remove the noise, one then has a problem with phase shift between $F(t)$ and $x(t)$. This sets an upper limit on the frequencies of functions $F(t)$ which can be employed.

If the initial value of $f_c(x)$ is not near the correct value, the circuit takes longer to approach the answer. If the value of B is not known accurately, it makes very little difference in the accuracy with which $f(x)$ is determined by the circuit. This is because B has only a minor effect upon the damped natural frequency of a second-order system. In a test of this point it was found that a factor 10 error in B produced no observed change in $f_c(x)$.

NEED OF RESEARCH ON IMPLICIT SYNTHESIS

Only a few circuits have been presented herein for common systems. There are many other systems of practical interest, and each contains several characteristics which could be obtained by implicit synthesis. Moreover, for finding any one characteristic there are many possible variations that one may design into the circuit in the interest of stability, accuracy, and freedom from noise. Several suggestions for needed research are presented in the following.

1. One could aspire to determine more than one characteristic per system equation. For example, one might try to determine B and K for a second-order system, or even M, B, and K. A possible approach would be to feed to the implicit synthesis circuit an additional derivative of the dependent variable for every additional characteristic desired. Another approach to be tried would be to make as many pairs of $F(t)$ and $x(t)$ tapes as there are characteristics to be determined, making sure that the functions $F_i(t)$ are sufficiently "independent" to convey different information, and having an implicit synthesis circuit for each characteristic. A third approach would be to replace an nth order differential equation by

the equivalent set of n first-order equations, in which could be determined one characteristic per equation.

2. In some cases of implicit synthesis it might be desirable to match $\dot{x}_c$ to $\dot{x}$, and/or even $\ddot{x}_c$ to $\ddot{x}$, as well as or instead of matching x_c to x, depending upon which quantities in the system can be measured accurately.

3. A common task will be to determine the functions comprising a term of the form $f(x)\times g(\dot{x})$ in a differential equation. Such a function occurs, for example, in Van der Pol's equation and in the dynamic equation for a landing gear.

4. Another challenge is to determine whether implicit synthesis can yield a characteristic in a small term, such as β in Duffing's equation:

$$\ddot{x}+\alpha x+\beta x^3=A\cos\omega t \tag{22}$$

or a small third derivative term in a system which is approximately second-order.

5. Work should be done to discover whether small nonanalytic nonlinearities may be determined by implicit synthesis. Examples are Coulomb friction, dead band, hysteresis, structural damping, mechanical stops, time delay, and the like.

6. An especially important class of problems today is the development of techniques for writing process equations and determining the characteristics.

7. Studies should be conducted to find out what can be done to supplement implicit synthesis by human trial and error, especially with respect to discovery of the most appropriate form for the differential equations describing a system, or with respect to determining more than one characteristic per equation.

8. Another possibility for research is to discover in what cases implicit synthesis could be accomplished on a digital computer or digital differential analyzer with better accuracy than on an analog computer.

9. Along with research on circuits and techniques, there must be developments in equipment, such as tape recorders and transducers having better linearity and less noise. There might even be a need for a photoelectric curve follower fed by an oscillograph roll. One may think also of the utility of special-purpose portable analog or digital computers for implicit synthesis of system characteristics in the laboratory, simultaneously with the testing of a system.

Implicit synthesis thus is a rich field for research and development studies conducted with computers. In such investigations, all equations and parameters should be nondimensionalized, if maximum economy of effort is desired. No one person or organization can hope to accomplish more than a small fraction of the studies that need to be made. Eventually, however, one may expect that there will be available a large catalog of trouble-free circuits for implicit synthesis of the characteristics of all systems having practical interest or important academic interest. Meanwhile, one may look forward to many interesting research papers in this field.

SOME PITFALLS IN IMPLICIT SYNTHESIS

The reader should note well that implicit synthesis is not yet ready for use by inexperienced or unwary computing engineers. There are many pitfalls, which are described in the following paragraphs.

PITFALLS OF STABILITY

1. Implicit computation with algebraic equations is known to be beset with pitfalls; implicit synthesis circuits are even more difficult to stabilize because the problem is dynamic rather than static.

2. When a least-squares circuit is interconnected with implicit synthesis circuits, the likelihood of stability problems is still greater.

3. Each implicit synthesis circuit adds its own transients which must be damped out quickly by means of additions of components to the circuit, such as capacitors and potentiometers.

4. Initial conditions must be selected with some care, to insure that the circuit will be able to proceed to the solution in a stable manner.

5. There are restrictions on the type of excitation function $F(t)$ which can be used, if instability is to be avoided.

6. The settling time of implicit synthesis circuits is variable and may be excessively long if too low a gain G is used.

7. In a digital computer or digital differential analyzer, the time increment Δt, used in conjunction with a given gain G, has an upper limit which must not be exceeded for stable operation.

8. An operational analog circuit has an upper limit on loop gain which cannot be exceeded without incurring undesirable transients or unstable operation.

PITFALLS OF ACCURACY

1. Noise in input signals $x(t)$ and $F(t)$ from tapes or transducers causes the answers to jump erratically, because implicit synthesis always involves one or more stages of differentiation.

2. If noise in the input signals is filtered, then accuracy is lost because of phase shift.

3. If the gain required for stability is too low, accuracy suffers.

4. In some implicit synthesis circuits, there is a steady-state error which increases as the dependent variable approaches zero.

5. In some implicit synthesis circuits under some conditions the settling time is so long that the transient gives an appreciable error.

6. $F(t)$ and $x(t)$ must be measured continually during a run and reported to the computer as a continuously varying voltage; if the inputs are known only at discrete times, the answers will be in error.

7. Scaling of an implicit synthesis circuit is critical if maximum accuracy is desired; it might be necessary in many instances to rescale several times.

8. Nonlinearity of tapes or transducers introduces error into the answer.

9. In a second-order system, the damping B cannot be determined accurately unless M and K are known with great accuracy; fortunately either M or K can be found accurately even if B is not known accurately.

The foregoing list of pitfalls is undoubtedly incomplete. Nevertheless, it should serve to arm computing engineers with a respect for the difficulties confronting development of any implicit synthesis circuit.

On the other hand, once a circuit has been found which works for a particular class of applications, and once the ground rules for its use have been set down on paper, implicit synthesis should be a reliable technique.

Dynamic Least Squares

The method of "dynamic least squares"[2] requires: 1. an implicit synthesis or differencing circuit, for determining the derivatives of the dependent variable, and 2. a least-squares circuit, for finding the characteristics. A linear second-order system will be used as an illustration of the method. One is given $x(t)$ from a system obeying the equation

$$M\ddot{x}+B\dot{x}+Kx=F(t) \tag{23}$$

in which M, B, and K are the characteristics to be determined. Assume for the moment that M, B, and K are known. Then $x_c(t)$ and its derivatives can be determined from an implicit synthesis circuit which compares $x_c(t)$ with $x(t)$, multiplies the difference by a large gain, and treats the result as a fictitious force which is used to correct $\ddot{x}_c$ directly and then indirectly $\dot{x}_c$ and x_c. After the implicit circuit transients die out, x_c and x should be nearly equal, the fictitious force should be nearly zero,and so x_c and its derivatives should be nearly correct. Accordingly, consider now that x_c and its derivatives are known. Then M, B, and K can be determined by least squares, so that the function $M\ddot{x}_c+B\dot{x}_c+Kx_c$ fits the given function $F(t)$ with minimum integrated error squared, i.e., one requires the time integral of ϵ^2 to be a minimum with respect to M, B, and K separately, where $\epsilon=M\ddot{x}_c+B\dot{x}_c+Kx_c-F(t)$. Then, by partial differentiation with respect to M, B, and K separately, and equating to zero, one obtains the following "normal equations" for determining M, B, and K:

Table I. Least-Squares Values

$$ {}^t_0\ddot{x}_c^2dt\ M+\int_0^t\ddot{x}_c\dot{x}_cdt\ B+ \int_0^t\ddot{x}_cx_cdt\ K=\int_0^t\ddot{x}_cF(t)dt \quad (24)$$

$$\int_0^t\dot{x}_c\ddot{x}_cdt\ M+\int_0^t\dot{x}_c^2dt\ B+ \int_0^t\dot{x}_cx_cdt\ K=\int_0^t\dot{x}F(t)dt \quad (25)$$

$$\int_0^tx_c\ddot{x}_cdt\ M+\int_0^tx_c\dot{x}_cdt\ B+ \int_0^tx_c^2dt\ K=\int_0^tx_cF(t)dt \quad (26)$$

If the characteristics are variable rather than constant, a digital computer can conduct a least-squares analysis on a running set of, say, ten points. In this way the characteristics can be determined in every time interval Δt after the first few. Then, they can be plotted against various possible arguments until each characteristic is a known function of a known argument. The same result can be achieved on an analog computer.

The foregoing procedure has been carried out in the simple case of a first-order system excited by a step function. The system obeys the differential equation

$$C_1\dot{x}+C_2x=F(t) \quad (27)$$

where C_1 and C_2 are constants, x is the dependent variable, and $F(t)$ is the forcing function (in this case, a unit step). This equation was set up in an International Business Machines Corporation 704, using the DIDAS (digital differential analyzer simulator) method for simulating a digital differential analyzer, and taking $C_1=1/7$ and $C_2=1$. Then, the $x(t)$ thus generated, together with $F(t)$, was subjected to analysis by dynamic least squares, which was also programmed by means of DIDAS. The Δt for the calculations was 0.001 second. After every 0.050 second, the results of the dynamic least squares determination of C_1 and C_2 were printed out and a new determination was started. Initially, both x and $\dot{x}$ were zero. After 0.500 second, the calculation was stopped. Similar runs were made with random white noise entering the integrals in the normal equations. The noise was limited to 1%, 2%, 5%, 10%, and 20% of the signal in the five runs made with noise. The values of C_1 and C_2 resulting from these least squares determinations were as presented in Table I.

From Table I, one notes at a glance that at least four significant digits were obtained correctly in each determination, even with 20% noise in the signals to the dynamic least-squares circuit. Thus the method of dynamic least squares can tolerate a large amount of noise without an appreciable degradation of accuracy in results.

A slight degradation may be noted in successive determinations. This is caused by the fact that at later times x is very close to unity and $\dot{x}$ is very close to zero, so that 50 values convey less information than did 50 values at earlier times when x and $\dot{x}$ were changing more rapidly. Moreover, a cumulative error arose in the generation of x.

One reason for the good accuracy in the foregoing results in that 50 points were included in each determination, which made most of the noise cancel itself out. The effect of including fewer points in each least-squares determination may be seen from the results in Table II, in which the noise was limited to 5%. The time increments were 0.001 second in all cases.

It is remarkable that even with only five points per least-squares determination, the results were correct to at least four significant digits, in spite of the 5% noise which was present.

Another series of runs was made with a sinusoidal $F(t)$ instead of a unit step. Again the time interval was 0.001 second. There were 50 points per least-squares determination. In the case of a period of 0.05 second, all values of C_1 were either 0.14285714 or 0.14285715, even for 20% noise. The values of C_2 ranged between 0.99999997 and 1.0000029.

It is believed that the foregoing results establish the validity and practical utility of the method of dynamic least squares for determining the constants in the differential equations representing dynamic systems.

Some Applications of Implicit Synthesis and Dynamic Least Squares

The analytical scientist and engineer are often faced with the problem of obtaining the characteristics in the differential equations representing a complicated system. In many instances there is no known satisfactory way to find one or more of the characteristics, chiefly because of the difficulty of analyzing the results of experiments in which more than one quantity is varied. Nevertheless, these scientists and engineers do the best they can, which might in some instances be a very crude approximation to the true characteristic. Not much is said publicly about such temporary failures of the experimental method, except when it is necessary to blame deficiencies of simulation upon the inadequacy of the equations and input data. Any simulation is only as good as the system equations and characteristics that one is given to work with.

The following offhand list is indicative of the enormous variety of applications awaiting the practical development of implicit synthesis and dynamic least-squares techniques:

AIRCRAFT AND AUTOMOTIVE INDUSTRIES

1. Determination of aerodynamic coefficients from flight tests involving complicated maneuvers; from dynamic tests in wind tunnels with elastic mountings; or from rocket sled tests.
2. Determination of the flutter speed of an airplane or missile surface from subcritical tests of airplanes in flight, wind tunnel flutter models, or rocket sled models, by determining the damping of the flutter mode as a function of frequency.
3. Determination of the flexibility characteristics of any structure.

4. Determination of servo internal characteristics and output impedance.

5. Determination of the characteristics of the interior ballistics of guns, rocket catapults, and the like.

6. Determination of the dynamic characteristics of tires.

7. Determination of the nonlinear dynamic characteristics of airplane control sticks, rudder pedals, and steering wheel linkages.

8. Determination of the dynamic characteristics of landing gears and automotive suspension systems.

9. Determination of the dynamic characteristics of turbojet, turboprop, reciprocating, free-piston, and all other engines, compressors, etc.

10. Determination of the parameters governing transient air flow through a porous material such as a fabric.

11. Determination of the course and speed of a target as an aid to tracking or fire control.

12. Determination of the characteristics of a "satellite" and its upper-atmosphere environment, with knowledge of the history of its motion (i.e., its orbit and perturbations).

13. Design of aircraft landing control systems, mid-air refueling systems, and other special purpose computers using prediction.

PROCESS INDUSTRIES: CHEMICALS, FUELS, MATERIALS, ETC.

1. Determination of the chemical kinetic and other parameters which determine reaction rates in batch or continuous processes.

2. Determination of: 1. the half-lives of the constituents, or 2. the composition, of a radiochemical mixture.

3. Determination of the dynamic rheological characteristics of materials undergoing deformation or flow.

4. Determination of the lumped parameters in sets of ordinary differential equations used to approximate distributed-parameter systems such as heat exchangers.

5. Determination of the characteristics of combustion processes.

6. Determination of neutron process parameters in nuclear reactors.

7. Determination of the dynamic parameters of instruments, transducers, and process control system components.

MISCELLANEOUS

1. Determination of dynamic parameters in biological population systems.

2. Determination of the characteristics of systems for which forecasts are to be made, such as dynamic economic systems (sales of a product, growth of a new industry, etc.).

3. Determination of the dynamic characteristics of a human operator of various devices when he is a part of a loop.

4. Determination of the dynamic characteristics of the regulatory systems in human or animal physiology.

Conclusions

Clearly, if an appreciable number of the foregoing possible applications do materialize, implicit synthesis and dynamic least squares will stimulate a major advance in the art of simulation. One will no longer be so bound by crude linearizations, steady-state representations, neglect of higher order derivatives, use of "eyeball" or "ballpark" values, and such approximations. One will be able to simulate some systems which have never been simulated before, such as complete dynamic human physiology.

If implicit synthesis and dynamic least squares become a practical reality, one may expect the use of transfer functions in systems engineering to yield its throne to a greater extent to the use of differential equations for the representation of nonlinear servos and other nonlinear mechanism in systems engineering.

Even if the applications of implicit synthesis and dynamic least squares are not so widespread as envisioned in the foregoing, one may expect them to form a new chapter in future books on computation.

There might well be important implications for the future of experimental science and technology, quite apart from providing imput data for simulation. To appreciate this possibility, one may look back upon the history of experimentation.

Consider first the field of static experiments, in which practical men seek a better process or material by varying factors to find the best combination. Traditionally this was done in accordance with the philosophy of "varying one thing at a time." because otherwise no one knew of any way to analyze the results. During the past half-century, thanks to the efforts of statisticians, methods have been developed for interpreting experiments in which many factors have been varied at once. In fact, the development of these statistical methods of analysis has permitted an entirely new philosophy of experiment design to spring into use. The modern theory of the design of experiments permits great economies on the number of experiments required by providing for the deliberate variation of many factors at once. As a dividend, the resulting information is far more accurate and broad in scope of validity.

In the same way, in the field of dynamic experiments it has been necessary to limit the generality of experiments, because techniques have not been available for analyzing the results of a general dynamic experiment. It is customary to set certain variables on zero or other standard values, restrict excitation functions to sine waves, unit steps, or ramps, and otherwise specialize each experiment, in order to permit data reduction. It is perhaps not too farfetched to conceive of implicit synthesis and dynamic least squares being commonly used to analyze the results of dynamic experiments and to display the desired characteristics of the system under study. If this takes place, it will lead to a minor revolution in the philosophy of dynamic experimentation, because it will relax restrictions on what can be varied and, indeed, will encourage deliberate variation, in order to investigate effects which do not appear under restricted conditions.

The ultimate in the application of implicit synthesis and dynamic least squares would be to conduct a single experimental run on an unknown system and to display as a result each characteristic of the system. The other extreme would be the conventional use of many experimental runs for the determination of each system characteristic, using paper-and-pencil or classical digital-computer methods of fitting discrete points for data reduction. In between these two extremes lies an interesting exercise in operations research. If the chief cost is from experimental time, then it would pay to invest a little money in computation in order to save experimental costs. This is clearly desirable in the case of jet engine testing, airplane or missile flight testing, rocket sled testing, nonproduction testing of a chemical plant, and so on. On the other hand, if the cost of making experiments is small compared with the cost of using a computer, then implicit synthesis and dynamic least squares would not be economical, though possibly still desirable.

All in all, the future possibilities of implicit synthesis and dynamic least squares are intriguing, even though the road has pitfalls. Surely the probability of success in at least a few applications, multiplied by the eventual payoff, is high enough to justify some research and development on implicit synthesis and dynamic least squares by nearly every organization which uses computers for the study of dynamic systems.

Nomenclature

A = amplitude of excitation in Duffing's equation
B = damping coefficient
C_1 and C_2 = coefficients to be determined
$F(t)$ = forcing function or excitation function
G = a large positive number
K = spring coefficient
M = mass coefficient
P = potentiometer setting
t = independent variable
x = dependent variable
y = refer to Fig. 9
α = coefficient of linear term in Duffing's equation
β = coefficient of cubic term in Duffing's equation
Δt = time increment in integration on digital computer
ϵ = error
λ = unknown constant to be determined
ω = frequency of excitation in Duffing's equation
τ = time constant

Subscript c means "computed value of"

The ON/K Carrier System

G. T. MASTERS
ASSOCIATE MEMBER AIEE

DUE to the recent growth of telephone requirements in northern California, a constant search is being made for better methods of using the basic telephone facilities in this area. One of the facilities which was looked at was the cable pairs used by the *K* carrier systems. This system, by design, is a long-haul carrier. That is, it is designed to provide circuits that have transmission characteristics suitable for 4,000-mile circuits. However, since the capacity of this system is only 12 circuits it was seen to be advantageous to devise some method to increase the capacity of the cable pairs. The circuits derived by such an addition could be short-haul, of 100 to 200 miles. The requirements for new long-haul circuits are being filled by the *L1*, *L3*, *TD2*, and in the future, *TH* carrier systems. The objective then of examining the *K* carrier cable pairs was to provide a method of deriving additional short-haul voice channels on these same pairs. One of the stipulations for any method of accomplishing this, however, is that no degradation of the *K* carrier systems should result from the modification or addition. A second stipulation, since the need for the additional channels was fairly urgent, is that any instrumentality employed should use as much existing equipment as possible in order to minimize the development time. With these factors in mind, a study was started which eventually led to the development of the *ON/K* system. This paper describes the development and the use of these systems in the northern California area of the Pacific Telephone Company.

The Development

Previous to this time several of the Bell System companies had stacked type *H* and other types of carrier systems under the *K* systems to provide single-channel service to points along the main *K* carrier route. However, the stacking of any carrier above the *K* system had not been attempted before this time. The Bell Telephone Laboratories became interested in this problem in response to a suggestion from the Northwestern Bell Company. An announcement was made to the operating companies about "putting the squeeze on the *K* cables," and a survey was made to see which of the operating companies would have application for such an arrangement. The results of the survey indicated that development of the system would be beneficial to several of the companies. The Northwestern Bell Company had an immediate need, and the Pacific Company would also require the system at an early date. These two companies agreed to loan engineering personnel to the laboratories during the development and field trials of the system.

The *K* carrier system has been described in previous papers.[1,2] A recapitulation of some of the basic characteristics is in order, to point up some of the problems encountered in the development of the *ON/K* system. The *K* system operates in the frequency range of 12 to 60 kc, using two cables, one in each direction of transmission. On cables of 19 gage, the repeaters are nominally spaced at a distance of 17 miles. It is necessary to provide special balancing arrangements to equalize the coupling between the pairs used for this carrier in order to minimize the crosstalk coupling. On the original *K* carrier systems, single-section balancing was employed, i.e., balancing equipment was provided at each repeater point. Later,

Paper 58-1005, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Pacific General Meeting, Sacramento, Calif., August 19–22, 1958. Manuscript submitted May 12, 1958; made available for printing July 10, 1958.

G. T. Masters is with the Pacific Telephone and Telegraph Company, San Francisco, Calif.

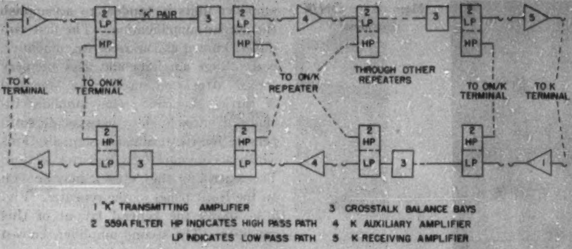

Fig. 1. Typical K carrier system equipped with 559A filters

it was found that several repeater sections could be balanced at a single point. This scheme is known as multisection balancing. Although single-section balancing provides the best over-all crosstalk suppression and is the arrangement used on most routes, multisection balancing offers certain economies and has been used on a few routes. A complete discussion of the methods of treatment for crosstalk is given in cited articles.

The first thing necessary to add channels to the *K* carrier cable pairs is to increase the frequency bandwidth of the repeaters. The present *K* repeaters have a bandpass of 12 to 60 kc. With the addition of 12 channels of *ON* it is necessary that the repeaters handle a bandwidth from 12 to 136 kc. One of the methods suggested to accomplish this was to modify a standard *K* repeater. Another was to use a *J* carrier repeater. These ideas proved impractical and were rejected. This then meant the development of a new repeater. The development objectives were kept in mind, and it was decided to retain the *K* carrier system in essentially its present form, and to develop the new repeater to pass only that portion of the band that was being added. This means that it is necessary to "split" the frequency band not only at the terminals but at each repeater point. A suitable filter to split the frequency band then became the next item for development. The Western Electric *559A* filter was designed for this purpose.

It can be shown that the addition of these filters in a crosstalk balancing section would upset the balance. Therefore, it was felt that this system should only be used in single-section balanced cables. Fig. 1 shows how these filters are placed in the line. The insertion of the filters on the line deteriorates the equalization of the *K* line, making it necessary to re-equalize the line. Previously, the standard method of equilization of *K* carrier lines utilized the incoming level of the pilots and test tones applied at the transmitting *K* terminal. This method was time-consuming, and had the additional disadvantage that the person making the equalization could not see the characteristics of the complete frequency spectrum of the *K* line at one time. This was because the receiving test equipment used during the test is capable of reading only one frequency at a time. Due to the amount of re-equalization to be done at present and in the near future, a new method of re-equalization was developed. The method which meets many of the requirements for re-equalizing *K* lines utilizes a spectrum analyzer, a pulse generator, a level monitoring meter, and a specially equipped portable *K* line amplifier.

The spectrum analyzer is a commercial test set made by Panoramic Radio Products, Inc. It can be adjusted to observe any portion of the spectrum up to 300 kc. Any signals present in the particular band chosen appear on a cathode-ray tube as vertical pips located horizontally in the order of their frequency. The amplitude of the individual pip is a representation of the power at that frequency. A picture of the unit is shown in Fig. 2.

The pulse generator is a 4-kc square-wave generator designed by the Bell Telephone Laboratories. Since the output of the generator is a square wave, it is rich in harmonic content. These harmonics are used for the re-equalization tests. When the generator is connected to a *K* line, the fundamental is below the band of the system, and the harmonics, one every 4 kc, are transmitted to the receiving end of the system. The harmonic output of the generator is essentially constant in the passband of the *K* carrier so that any variation in level that is noted at the receiving end is due to the characteristics of the line.

The level monitor meter is a simple thermocouple meter designed by the laboratories and is used to provide a constant check of the over-all line level during re-equalization.

To provide a rapid method for substituting all of the available equalizers into a *K* line being re-equalized, a portable *K*-line amplifier was equipped with all the possible equalizers available on a switched basis. Fig. 3 shows the complete amplifier and equalizer. In addi-

Fig. 2. Panoramic spectrum analyzer

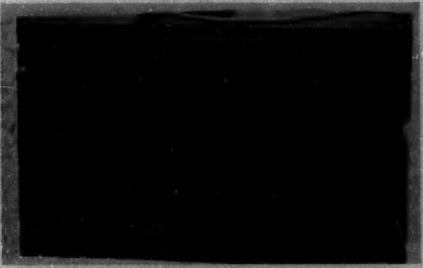

Fig. 3. Amplifier-equalizer equipment

Fig. 4. ON/K terminal

tion, a photographic method of recording data was developed which simplified both the data-taking and analyzation.

The pulse generator is placed at the transmitting *K* terminal on the section to be re-equalized. The special *K* amplifier is patched in place of the regular *K* amplifier and the equalizer controls adjusted until the proper equalization is observed on the spectrum analyzer connected to the output of the amplifier. The strapping on the regular amplifier is then changed to agree with the settings obtained on the test amplifier. The regular amplifier is then placed back into the line, and a check made with the spectrum analyzer to verify the equalization. Photographs of the spectrum analyzer presentation may be taken at any time to be used for comparison or record purposes.

The Terminal

The *ON/K* system in its present form uses a portion of the standard *ON* terminal. The *ON* carrier system has been covered in a previous paper;[3] therefore, no detailed description will be given here. Fig. 4 shows a typical installation of the *ON* terminal equipment as used for the *ON/K* system. Due to the frequency restriction imposed by the available band, it is impossible to use the complete *ON* terminal, and presently only three groups are used for this application. This arrangement gives a gain of 12 channels. In the near future the *ON* terminal is to be modified. It presently has five 4-channel groups but the change will result in six 4-channel groups. At that time, 16 channels may be obtained when using this terminal equipment for *ON/K*. Arrangements are available to extend the *ON/K* systems over open wire or *N* carrier cable pairs by the use of *ON* or *O* junction equipment. When the modified *ON* terminal is used, the ability to interconnect with *O* carrier is lost, so this system can be extended only over cable facilities.

The Repeater

The repeaters used in the *ON/K* system are one of the most interesting features of the system. It was not practical to interset repeaters in the *K* repeater section to amplify the *ON/K* band because of the crosstalk balancing arrangement. It becomes necessary to design a repeater that will properly amplify the *ON/K* signals for transmission over the complete *K* repeater section. The loss of a standard *K* repeater section at the frequency of operation (80 to 136 kc) is approximately 100 decibels. It was decided to use two amplifier units in tandem to accomplish the needed amplification. The first amplifier, known as the receiving amplifier, is a voltage amplifier and uses circuitry copied after that used in a standard *N* carrier repeater. This amplifier includes a variable slope network to compensate for the residual misequalizations which accumulate in a repeater section. The control for the network may be seen on the front panel of the repeater. Fig. 5(A) shows the general layout of this amplifier. The second amplifier, known as the transmitting amplifier, is a power amplifier. This unit has an output of +20 decibels referred to 1 milliwatt, and is self-regulating to keep the output constant. The regulation is accomplished by a thermistor-controlled network in the feedback path of the amplifier. Fig. 5(B) shows the layout of this unit.

The packaging of these amplifiers was another example of the development-saving methods that were used on this system. The die-cast stampings that are in use for the twin channel modules of the *O* carrier were used for these amplifiers with only minor changes. This meant that no new dies or other fabrication machinery were needed to produce the amplifier or power module mountings. Fig. 5(C) shows one of the repeater mountings with the amplifiers and power module in place.

The filament supply for these amplifiers is alternating current, as in the standard *K2* repeater. A transformer that is mounted at the top of the equipment bay is used to change the 60 volts used for office distribution to 19 and 6 volts for the filaments. The 60 volts used for office distribution are normally obtained by the use of a transformer from standard commercial power sources. In the event of a commercial power failure, the filament supply is switched from the commercial mains to an emergency vibrator supply which operates from the office battery. The plate supply for both of the amplifiers is obtained from the office batteries. At a *K* auxiliary station the plate supply is 152 volts. At *K* main stations the common plate battery is 130 volts. This voltage is adequate for the receiving amplifiers but the transmitting amplifiers need the higher voltage in order to provide the output power required. To obtain 152 volts at *K* main stations, it was necessary to put the negative 24-volt supply in series with the 130-volt supply. A terminal block with movable links is provided in the power module to make the necessary voltage connections for either auxiliary or main station use. The power

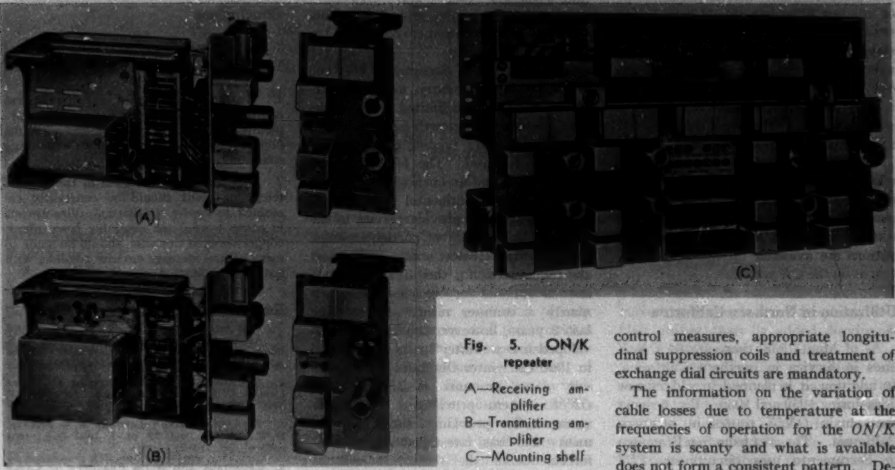

Fig. 5. ON/K repeater

A—Receiving amplifier
B—Transmitting amplifier
C—Mounting shelf

module also contains the necessary fusing and alarm circuits for the repeater mounting. It may be seen in the pictures of the unit that pin-type jacks are provided for the in-service measurement of all voltages used by the repeater. It will also be noted that there are four pin jacks on the front of each amplifier. These are used to make in-service tests of the condition of tubes in the amplifiers.

On repeater sections shorter than the nominal distance, it is necessary to use some networks to build out the section electrically to the length of a standard repeater section. These networks are normally placed between the receiving and transmitting amplifier. This gives an advantage in signal-to-noise ratios. On very short sections where large amounts of build-out are required, a portion of the network can be placed before the receiving amplifier to prevent overloading. The networks used in this application are the same as those that were designed for the *N* carrier system. The space for mounting an adequate number of networks to care for most applications is provided in the repeater mounting unit. This space can be seen between the terminal strips in Fig. 5(C). On short repeater sections an auxiliary panel is supplied to mount the additional networks.

Transmission Characteristics

The over-all transmission characteristics of the system are comparable to those of the *N* or *ON* carrier systems. The channel noise and crosstalk objective is 26 decibels adjusted at the zero level point on systems up to 200 miles. Experience has proved that these values have been attained or bettered on the *ON/K* systems now operating. Due to the low line levels encountered, down to −80 decibels referred to 1 milliwatt, extreme care is necessary in the wiring layouts. Special shielding practices have been developed and the placement of the office wiring is carefully specified in the installation procedures. The *K* cable pairs must be examined for proper noise control measures, appropriate longitudinal suppression coils and treatment of exchange dial circuits are mandatory.

The information on the variation of cable losses due to temperature at the frequencies of operation for the *ON/K* system is scanty and what is available does not form a consistent pattern. Design calculations indicated that the regulation deviations encountered in the *ON/K* system would be similar in magnitude to those in a normal *ON* system on distances up to 200 miles. Experience has shown that circuits obtained from this system are entirely adequate in this respect for short-haul usage. For those systems that do not perform properly or for systems in excess of 200 miles in length an adjustable deviation equalizer has been provided. With the use of this equalizer several systems of lengths up to 400 miles have been planned.

Because of the misequalization caused by the addition of the *559A* filters in the *K* system lines, no more than 500 miles

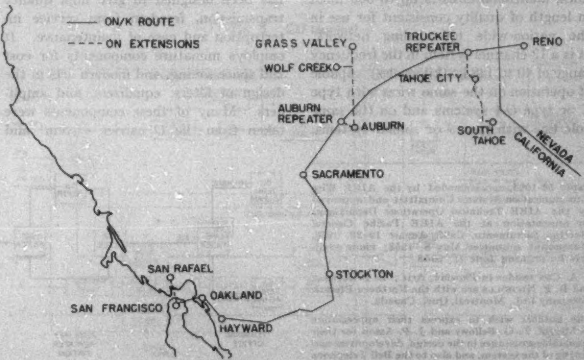

Fig. 6. ON/K routes in northern California

of any one *K* system should have *ON/K* systems operating above it. This restriction will not ordinarily hamper the operation of the *ON/K* system in any one Bell System operating company, but it will mean that careful co-ordination will be necessary between companies to see that this limit is not exceeded.

The gain frequency characteristics, mainly controlled by the channel terminal equipment, are the same as those observed on a normal *ON* system. Of course, the same levels and signalling options are available on the *ON/K* system as on the *ON* system.

Utilization in Northern California

As of May, 1958, there are 64 *ON/K* lines in service in northern California. In addition, it is planned to add 21 new lines during 1959 and 1960. Fig. 6 shows the main *ON/K* routes in northern California. The area from San Francisco to Sacramento uses circuits on *TD2* radio, *N* carrier, *ON* carrier, and *ON/K* carrier to meet the requirements. The use of *ON/K* carrier for a portion of these requirements has allowed a deferment of other and more expensive types of route reinforcement and has provided another means of diversification of routing for the protection of service.

The area east of Sacramento to Reno is mountainous country and the telephone facilities are limited. There has been considerable growth in this area in the last few years, tending to exhaust all available facilities. The few voice frequency pairs and an open-wire lead, part of the old transcontinental wire, are the basic facilities to provide service to the area. A community of particular interest is the Tahoe resort area. In the past the requirement for this area was above normal but was very seasonal; it is primarily a summer resort. During the last 2 years, however, this area has developed into a winter sports center, and in 1960 the winter Olympics will require very large amounts of service. The *ON/K* system provides a means for economically providing these requirements and has forestalled costly reinforcements of the route. It will be noted that all of the communities of interest served by this route are not on the main cable; therefore, many of the *ON/K* systems are extended to these points by means of *ON* carrier.

Conclusions

The experience gained during the use of the *ON/K* systems has proved again that:

1. By judicious use of existing instrumentalities the necessity for new development can often be minimized, and all of the objectives still be gained, in an expanding communication network.

2. The basic facilities used in the present telephone plant should be constantly examined to assure maximum utilization or, in other words, the available basic plant, copper wires in this case, should be made to carry all the message circuits possible, with economic limitations always in mind.

THE OJ carrier system is designed to provide economically, on open-wire lines, additional circuits up to 500 miles in length of quality consistent for use in the nation-wide toll dialing network. It is a 12-channel system in the frequency range of 40 to 148 kc (kilocycles), capable of operation on the same wires with type *C* or type *OA* systems and on the same pole line with type *J* or similar systems. It is intended for the same field of use which type *J* has filled successfully and has been designed to give high quality transmission, freedom from service interruption and ease of maintenance. It employs miniature components for cost and space saving, and modern arts in the design of filters, equalizers, and amplifiers. Many of these components were taken from the *O* carrier system[1] and hence the designation *OJ* for a system similar to *O* in its composition and occupying the type *J* field.[2]

The longer and more important open-wire lines usually have *J* carrier systems on some of their wires. Type *O* systems, employing a frequency allocation not compatible with *J*, cannot be added to such lines for any considerable distance. *OJ* however can be added and can also be extended out over branch lines or can readily be connected to *O* systems on such branches or to type *ON* carrier[3] in cable extensions. When so desired, circuits can be dropped or branched in groups of four at any repeater point.

A typical *OJ* carrier application on a

line in association with an *OA* system to derive a maximum of 16 carrier channels is shown in Fig. 1.

As in *N* and *O* carrier systems, the assembly of the units is designed for a maximum proportion of wiring, testing and adjusting to be done in the factory and with a minimum of field engineering and installation effort. Die-cast frameworks for units and mountings insure mechanical rigidity and good fit between parts.

Frequency Allocation Plan

The frequency allocation of the *OJ* system is shown in Fig. 2. W-E (west-east) transmission in the range 40 to 88 kc and E-W (east-west) transmission in the range 100 to 148 kc co-ordinates with the type *J* allocations. The frequency space below 40 kc is left clear for *C* or *OA* carrier. Twin-channel operation, that is, the transmission of two channels as the sidebands of a common carrier, requires the generation of only one carrier frequency and the provision of only one gain regulator per two channels. The discrimination required of the channel band filters is less by this method of operation since the carriers are 8 kc apart and the unwanted energy that gets through the band filter from some other twin will demodulate as frequencies above 4 kc. These can be removed by a simple voice frequency roof filter rather than by added discrimination in the channel band filter.

By taking advantage of built-in compandors, as described in papers on the type N^4 and type *O* carrier systems, it has been possible to reduce the side-band energy transmitted to the line very substantially without the system becoming oversensitive to noise and

crosstalk. The compandor advantage also makes it unnecessary to stagger frequency allocations as was done in type *J*, to reduce intersystem crosstalk.

As in the type *O* system the channel carriers are transmitted at a reduced level and employed at the distant terminal for channel regulation and for demodulation. Since the modulation at one terminal and the demodulation at the other are accomplished by the same carrier, the channel output is returned to the exact frequency of the input, regardless of intermediate frequency translations.

The elimination of staggered systems and the relaxed requirement for synchronization simplify the carrier supply to such an extent that its provision on a per terminal basis instead of in common for an office is economical. This is particularly useful since future demand for *OJ* systems is expected to tend toward smaller numbers of terminals at one place and time. To facilitate engineering and installation, the terminals have been made completely independent, with no common equipment.

Modulation Plan

The modulation plan of the *OJ* system is shown in Fig. 3. The 12 channels are arranged in three groups of four channels each. In each of these 4-channel groups, four single side-band carrier channels are generated: one as the upper sideband and one as the lower sideband of a 184-kc carrier; one as the upper and one as the lower sideband of a 192-kc carrier. The four modulated outputs are combined with resupplied reduced level carriers to form a 4-channel band in the frequency range 180 to 196 kc. Modulation with a group carrier in a group transmitting unit places this band in the proper frequency range and at the proper level for transmission over the line. The channel carrier frequencies are transmitted to the line at 0 decibels referred to one milliwatt, the message and signaling tone level in the sideband is −2 decibels.

Regulation

Gain regulating range is provided in the repeater and terminals to compensate for line transmission loss variation with weather from dry to wet and to 1/4-inch radial thickness of ice. Flat and slope regulation are provided at each repeater and in the receiving side of each terminal. The highest and lowest carriers in the W-E band, 84 and 44 kc, and in the E-W band, 144 and 104 kc serve as pilot tones. Flat regulation is by means of a variolosser controlled by the sum of the two pilots; slope regulation, by means of a variable slope equalizer controlled by the difference of the two pilots. Mop-up regulation and equalization is provided in the twin-channel units, controlled by the carrier for each pair of twin channels.

Terminal

Fig. 4 shows an *OJ* 12-channel terminal. The principal assemblies are from top to bottom: mounting and units for channels 1 to 4, the same for channels 5 to 8 and for 9 to 12 and finally the amplifier-regulator in the common receiving circuit. Fig. 5 is a block schematic of an *OJ* terminal, divided into functional areas. Each of these areas is also a physical unit or sub-assembly. In the following description, those parts previously described in the paper on the type *O* carrier telephone will be passed over briefly and more attention given to those peculiar to *OJ* carrier.

Each channel unit, Fig. 6, consists of three subassemblies; the compressor, the expandor and signaling circuit, and the carrier frequency circuit. The built-in 3,700-cycle out-of-band signaling for the transmission of dialing and supervisory signals, is optional. This signaling system has been described in the papers on *N* and *O* carrier systems.[1,4] The channel units are identical with those of *O* carrier. Briefly they include the compandor, the signaling circuit, the modulator, demodulator, and associated channel band filters.

A twin-channel unit, Fig. 7, like that of type *O*, includes the oscillator supplying modulators of two channels with 184-kc or 192-kc carrier frequency, the pick-off filters and amplifier supplying the demodulators of the same two channels with carrier frequency taken from the line, and the receiving channel gain regulator.

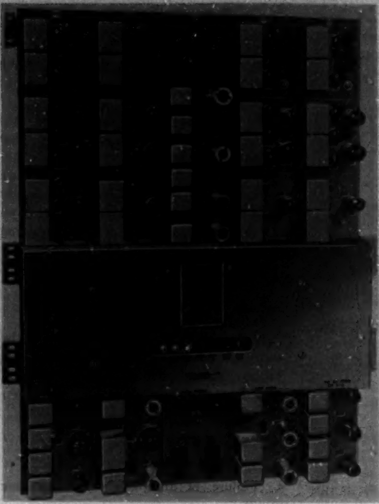

Fig. 10. Four-channel group assembly

Each of the three group transmitting units, Fig. 8, consists of a modulator and associated filter which places a basic 4-channel group in the proper location in the line frequency spectrum, and a 2-stage feedback amplifier, with relatively flat transmission from 40 to 148 kc. This unit also includes a noise generator from which a controlled level of noise is introduced into the receiving side of the system to mask intelligible crosstalk during silent intervals. Each group oscillator unit, also shown in Fig. 8, supplies two carrier frequencies one to the modulator in the group transmitting unit, the other to the demodulator of the group receiving unit. The group oscillator unit also contains a 3,700-cycle oscillator supplying signaling frequency to the four channels of the group.

The group receiving unit, Fig. 9, comprises a group receiving filter which selects one of the three 4-channel groups, the demodulator which translates the group from its line frequency allocation to the basic group frequency band, 180 to 196 kc, a demodulation filter to remove unwanted modulation products and a two stage amplifier. Noise from the noise generator in the group transmitting unit is introduced at the output of the group demodulator to mask intelligible crosstalk as previously mentioned.

Fig. 10 shows the 4-channel group terminal assembly, comprising four channel units, two twin-channel units, the group transmitting unit, group oscillator unit, and group receiving unit.

Amplifier-Regulator

The amplifier-regulator, Fig. 11, provides flat and slope regulation to compensate for line loss variation with weather. It is connected in the receiving side of the terminal and is also used as the E-W and W-E halves of the repeater. Its regulating range is adequate for approximately 33 miles of sleet covered line (1/4-inch radial ice) or upward of 100 miles of wet line.

The highest and lowest frequency channel carriers in each 12-channel band (44 and 84 kc in the W-E direction and 104 and 144 kc in the E-W direction) are used as pilots. They are picked off at the output of the amplifier-regulator, their sum used to control the flat gain and their difference to control the slope gain. The combined action is such as to maintain the amplifier-regulator output at a fixed level, constant across the frequency band.

As indicated in Fig. 11, the two pilots are selected from the through transmission circuit, and fed to the flat and slope control units. In the slope control unit, Fig. 12, each pilot is amplified by a 2-stage feedback amplifier and rectified. The resulting d-c voltages are connected series opposing to the input of a single stage d-c amplifier. The plate current of this amplifier passes through a thermistor which is the controlling resistance element of a variable slope network. A small difference in the two pilot currents controls a relatively large change in the thermistor current and swings the network characteristic from maximum slope in one direction, to maximum slope in the other, as indicated by the variable equalizer characteristics, *A* and *B*, in Fig. 13 (low group) and Fig. 14 (high group). An associated fixed equalizer has a fixed negative slope, as shown in Figs. 13 and 14. The sum of the fixed and variable slope equalizers provide a combined frequency characteristic, also shown in Figs. 13 and 14, which may be varied from flat loss across the frequency band to a slope of 30 db in the high frequency range or 18 db in the low frequency range. The regulating action sets the equalizer so as to keep the high and low frequency pilots equal at the amplifier-regulator output.

The action in the flat control unit, Fig. 15, is similar except that the sum of the two pilots is amplified and rectified. The resulting direct voltage is opposed to a constant direct reference voltage and the difference is impressed on the input of the d-c amplifier. The plate current of

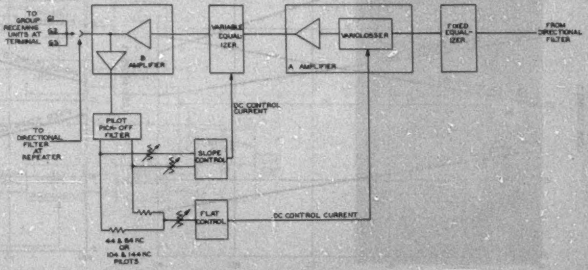

Fig. 11. Amplifier-regulator

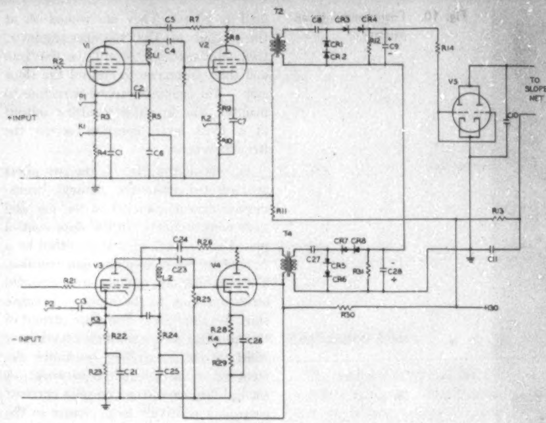

Fig. 12. Circuit of slope control unit

this amplifier passes through a variolosser shunted across the main transmission path. The loss in this unit is thus adjusted so that the total output of the amplifier-regulator remains constant. The bias voltage is stabilized by an avalanche diode.

The variolosser, Fig. 16, consists of a pair of diffused silicon diodes connected opposing in shunt across a relatively high impedance circuit. With no direct current flowing the a-c impedance of this shunt is very high so that negligible loss is introduced. As the direct current increases the a-c impedance falls. The range of direct current employed in the *OJ* unit is approximately from 0.01 to 12 milliamperes with a resultant a-c shunt impedance of 3,000 to 10 ohms and an insertion loss of 10 to 55 db. Interchannel modulation in this circuit has been reduced by the introduction of a capacitor at the midpoint of the output transformer. Without this capacitor the effect of any unbalance between the two diodes is amplified by d-c flow through the shunt path afforded by the transformer winding.

By the combined action of the two control units, the one adjusting the slope to keep the two pilots equal, the other adjusting the flat loss to keep their sum constant, the line loss is automatically built out to give a constant output from the amplifier-regulator to the outgoing line at a repeater or to the group receiving units at a terminal.

Alarm Circuits

Alarm circuits are provided in the terminal mountings to give individual visual indications of the following troubles:

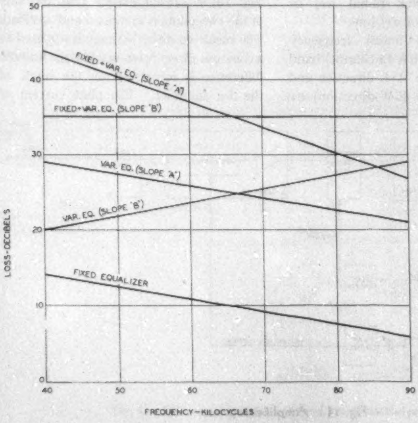
1. Failure of the 48-volt fuse
2. Failure of the 130-volt fuse
3. Loss of incoming carrier
4. Failure of the 3,700-cycle signaling supply

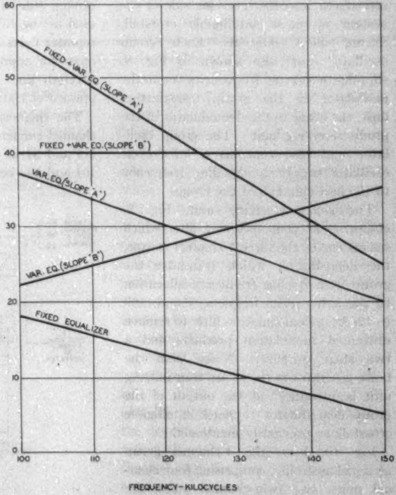
Provision is also made for operating the central office visual and audible alarms. These alarms can be cut off by operation of an "Alarm Release" key. Visual and audible warning will again be given when the system is restored to service.

In the case of 3,700-cycle or carrier failure, the alarm circuit opens the *E*

Fig. 13 (below). Frequency characteristic of low group equalizer

Fig. 14 (right). Frequency characteristic of high group equalizer





leads to the office supervisory or dial equipment, to give called subscribers a chance to disconnect their telephones. After an interval of about 10 seconds, controlled by the operation of a thermal relay, ground is supplied on the *E* leads to the office equipment making the channels appear busy. Failure of one terminal automatically causes an alarm condition at the distant terminal by removing the carrier supply for a short period.

The carrier fail relay, which is located in the amplifier-regulator mounting, is held operated by a direct current derived from the amplified and rectified carrier pilot frequencies at the output of the flat control unit. Loss of these pilot frequencies releases the relay and causes the alarm circuits in the three terminal mountings to operate. A 3-second delay circuit insures that the "Carrier Fail Alarm" circuits will not operate as the result of very short duration line faults, and also serves as a precaution against accidental restoration due to noise or crosstalk.

Circuits are also provided whereby the system may be transmission tested from either terminal prior to returning the system to service. This feature which is also provided on *O* carrier enables maintenance personnel to check whether trouble has been cleared, before trying to restore the system. It is particularly useful in the case of line trouble which may occur for a short time and then clear itself.

The transmission test is made possible by looping the signaling circuit on the first channel of each group. Signaling tests can then be made from either terminal through the loop, visual indication being given if the test is successful.

A remote restoration feature enables the distant terminal to be restored to service from the near end. Operation of a "System Restore" key restores the near end terminal and transmits signaling tone over the fourth channel of each group. At the distant terminal this tone will cause a thermal relay to operate, restoring that terminal to service. The delay period afforded by this relay prevents faulty restoration due to crosstalk or noise.

Repeater

As indicated in the block diagram, Fig. 17, and in Fig. 18, the repeater is made

up of two directional filters and two amplifier-regulator units. The directional filters are alike, requiring simply to be properly oriented in their sockets for the *E* or *W* side of a repeater. The amplifier-regulators are alike except for the pick-off filters and equalizers which are plug-in units designed for the high-frequency (E-W) or low-frequency (W-E) range.

The repeater has a maximum gain of approximately 60 db at the highest frequency. The regulating range is approximately 30-db slope in the high frequency band and 18-db in the low frequency band. Flat regulation at mid-frequency of either band is approximately 45 db.

Lines and Line Equipment

The requirement for crosstalk separation between type *J* systems was established at 59 db. In order to meet this requirement not only was very precise line construction necessary but also the provision of staggered frequency systems. The inclusion of compandors in the type *OJ* systems reduced the separation requirement so that good performance may be expected if the minimum effective equal level far end coupling loss, including reflected near end coupling, is 47 db between pairs one of which is used for a *J* system and one for an *OJ* system or 34 db between two pairs both used for *OJ* systems. This assumes the use of masking noise on the *OJ* systems.

As a result the provison of staggered systems is avoided, simplifying engineering, manufacture and maintenance. Type *O* transpositions may be used unless there are *J* systems on the line. In general, crosstalk and noise requirements are met somewhat more easily than with *J* systems.

Repeater spacing is about the same as for Type *J*, that is 40 to 45 db where the layout is based on wet weather line losses or 60 db where the layout is based on sleet. Care is needed in impedance correction at open-wire to cable junctions, including intermediate cables at river or railroad crossings or through towns, since reflection at such points converts unobjectionable near-end crosstalk into interfering far-end crosstalk.

Of the various line equipment arrangements used at terminal and repeater offices, the two shown in Figs. 19 and 20 are the simplest. In Fig. 19 both the higher frequency *OJ* system and the lower frequency *OA* system, or a *C* system plus voice, are brought in on the same cable pair and separated by a line filter in the office. Autotransformers are used to match the open wire impedance to that of the cable at the line terminal pole and the cable to the office equipment. This provides a good match at carrier frequencies but is not very satisfactory at voice frequency. In Fig. 20 the line filter is placed at the terminal pole, the *OJ* system brought into the office on a nonloaded cable pair and the *OA* system or a *C* system plus voice on a *C* loaded cable pair. This arrangement is preferable for a voice circuit equipped with a repeater. In either arrangement the longitudinal inductors at the end of the open wire suppress longitudinal voltages induced on the line and assist in lightning protection.

System Performance

Fig. 21 is a typical over-all frequency characteristic of a message channel. Four such channels in tandem, as might occur in a built up connection, would show an attenuation at 250 cycles of about 10 db as compared to the 1,000-cycle transmission equivalent and at 3,000 cycles about the same amount. In the field trial satisfactory conversations

Fig. 21 (below). Over-all frequency characteristic of OJ message channel

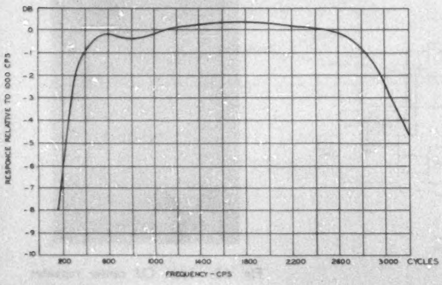

Fig. 22 (right). Limiting load capacity of OJ channel

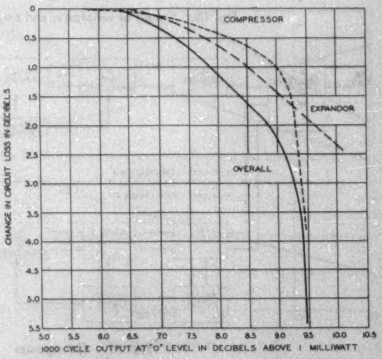

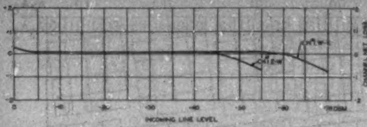

Fig. 23. Transmission regulation of OJ channels with line transmission loss variation

were carried on over eight links in tandem, which is twice the maximum number that might conceivably occur in practice.

The operation of a multichannel carrier system is improved by designing into the channel circuits an amount of power limiting determined by experience. The extent to which power peaks are limited in the *OJ* system is shown in Fig. 22. A very strong talker (zero volume units) will have a peak 10 db above the rms value about 1/10th of 1% of the time. This is about the limiting peak of the system.

Circuit noise from the terminal and repeater equipment are low, so also is line noise during normal operating conditions with no "static" fields due to storm conditions or excessively low line levels due to ice. To mask crosstalk during silent intervals background noise is introduced at the receiving terminal about 57 db below a loud or zero volume units talker. During thunderstorm periods along the open-wire line noise peaks caused by static may rise 15 db or more depending on the severity of the storm and its location relative to the line.

Crosstalk between channels of one system is controlled by circuit and equipment design. Crosstalk between channels of adjacent systems is affected also by the transposition design, line construction and other factors outside the system equipment. Both are greatly reduced by the use of compandors in the *OJ* system. In general the crosstalk from all sources either between channels of one system or between channels of adjacent systems with properly designed and constructed lines should be 60 db below zero level speech.

Fig. 23 shows the output level of a 1,000-cycle tone as a function of its input level for the two channels transmitted at highest and lowest line frequencies, the curves represent the over-all regulation including that of the flat and slope controls in the amplifier regulator and that of the channel regulator in the twin-channel unit.

Field of Use

Open-wire carrier circuits are unlikely to be used between regional centers or from regional centers to sectional centers, since facilities on these back-bone routes will be provided by microwave, coaxial or cable carrier. It seemed improbable, therefore, that *OJ* circuits will be required longer than 500 miles and this length was therefore chosen as the design objective. There is, however, no inherent limitation that will prevent use at somewhat longer distances, particularly where static field intensities are ordinarily low, as in Canada and parts of the United States.

Field Trial

A field trial of the *OJ* carrier system was held during a 6-month period, over Bell Telephone Company of Canada facilities. The trial system, comprising two terminals and two repeaters, was operated over a 150-mile length of *J* transposed line. Other *J*-type carrier systems occupied neighboring positions on the line.

Transmission tests were made over the 150-mile route, and also over longer distances by looping channels together at the 4-wire VF jacks. Regulation tests were carried out by inserting sections of artificial line to simulate the effect of sleet. Crosstalk tests, carried out with the assistance of Bell Telephone Company engineers, indicated that crosstalk into, or from, the *OJ* system was satisfactorily low. In every respect, the field trial results indicated that the design requirements for the *OJ* system had been adequately met.

Diagrammatic Methods of Code Construction

ROBERT C. CLARK
ASSOCIATE MEMBER AIEE

INCREASED USE of automatic operating techniques has created a greater demand for communications links to be used for telemetry, selective remote control, and supervisory control. Supervisory systems which had gained wide acceptance in electric utility operations have been applied to oil pipe lines. In a manner, these operations are also related to ticket reservation equipment used by railroads and airlines, and to transmitter remote supervision equipment used by standard broadcast stations. There are undoubtedly other examples. Whereever a commercial operation exists requiring very little human effort but constant human surveillance, fail-safe automatic equipment can be developed, and the operation can be supervised from a centralized remote-control location.

All remote-control and supervisory circuits impose a common demand on their communications links: the total number of different messages to be transmitted is relatively small, but a transmitted message must be received and decoded at the far end of the link with extremely high reliability. The degree to which this statement is true will depend in each application on the number of different operations or trouble indications involved, and the importance assigned to each of these operations and indications.

Paper 58-997, recommended by the AIEE Telemetering Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE-IAS-ARS National Telemetering Conference, Baltimore, Md., June 2–4, 1958. Manuscript submitted May 20, 1957; made available for printing May 20, 1958.

ROBERT C. CLARK is with the General Electric Company, Syracuse, N. Y.

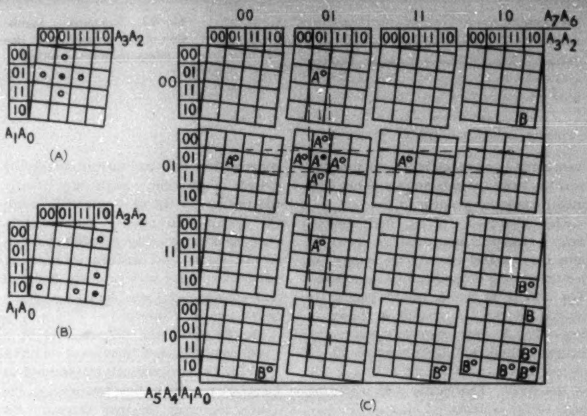

Fig. 3. Examples of single-digit error indication on Karnaugh-Veitch maps. A—Code 0101. B—Code 1010. C—Codes 01010101 (A) and 10101010 (B)

A communications link always has some noise, the presence of which implies a certain probability that the received message is false. For a given average noise power, this error probability can be made arbitrarily small by applying one or more of three techniques:

1. The increase of signal power for more favorable signal-to-noise ratio.
2. The development and use of more efficient schemes of demodulation.
3. Encoding of the messages so that a great amount of noise distortion is required before one message looks like another.

This report deals with the last method of reducing error probability. In particular, it will discuss diagrammatic methods of code construction, and approximate equations whereby the reliability improvement may be evaluated.

The methods discussed here have been evolved as a result of studies relating to time serial binary coding transmitted on a nonreturn-to-zero basis. A typical code transmission is illustrated in Fig. 1. In this coding scheme, a fixed number of equal successive time intervals are assigned "1" or "0" values, independent of adjacent intervals. Each interval, then becomes a digit of a binary number which may be used to represent the message. In general, all messages of a system consist of the same number of time intervals or digits. Teletype systems use this coding, with 5- or 6-digit messages. Actually, these methods of analysis are not limited solely to such codes; they may be used for any coding scheme involving a fixed number of two level inputs, where it is valid to assume that the average correlation between noise of any two separate inputs is zero.

Code-Mapping Techniques

THE 3-DIMENSIONAL MODEL OF N-DIMENSIONAL BINARY CODING SYSTEMS

Hamming[1] introduced the distance protection concept for coding messages to reduce error probability. He has described precisely the procedure to be used for producing single-error detecting or correcting codes and single-error correcting, double-error detecting codes with a minimum addition of code checking and correcting digits to the required message digits. For purposes of explaining the distance protection principle, a 3-dimensional model of a 3-dimensional (or 3-binary-digit) code system, shown in Fig. 2(A), is often used. Each of the three axes of the model is assigned to a single digit. Since each digit can have only two values, all values of the 3-digit function are represented on the eight corners of the cube. Error in a single digit will result in motion along a line of the cube from one corner to the next, e.g., an error in the A_1 digit of code 0010 will result in code 0000. (The order of code digits in this report is identical to that used for conventional number representation, i.e., $A_n \ldots A_2A_1A_0$.)

R. D. Berlin of the General Electric Electric Company has suggested a procedure for extending this model to four or more digits. It will be noted that the corners of the 3-digit model, Fig. 2(A), are labeled with four code digits, the A_3 digit being zero in all cases. This is valid, as the cube can be considered an equipotential surface to any additional code model; then, it is necessary to provide two of different size, assign each cube one of the two values which the fourth digit can assume, and connect corresponding corners of these cubes to form the 4-digit model. This figure may be considered to have 16 corners, representing the 16 possible 4-digit combinations, and four paths intersecting at each corner, representing the four directions by which a single digit of distortion can alter the combination.

The same concept of equipotentiality may be applied to constructing a 5-digit model as shown in Fig. 2(C). There is no limit to the number of digits which can be built into the model, except that the model becomes increasingly cumbersome. This model is used here chiefly to illustrate a technique whereby dimensionally limited systems can be extended to a form usable for studying the multidimensional systems involved in coding.

KARNAUGH-VEITCH MAPPING TECHNIQUES

In their discussions of switching systems and of coding, Keister, et al.,[2] demonstrated that hypercubes and connected hypercubes were a valuable analytic tool. Veitch[3] and Karnaugh[4] have demonstrated a mapping technique based on the hypercube, applying it chiefly to minimization of switching circuits. Caldwell[5] used this map to demonstrate the recognition of symmetric switching functions. O'Brien[6] demonstrated the value of this mapping technique for selecting

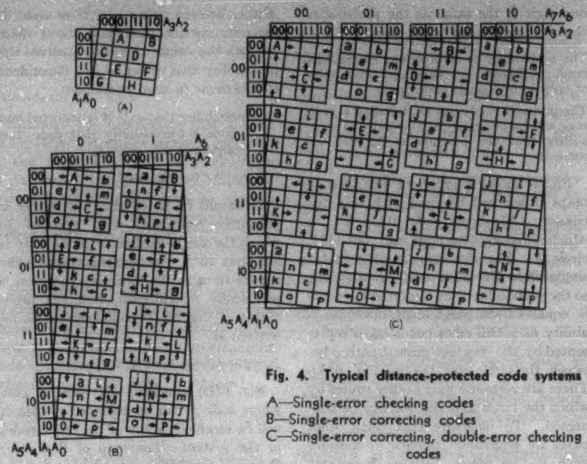

Fig. 4. Typical distance-protected code systems

A—Single-error checking codes
B—Single-error correcting codes
C—Single-error correcting, double-error checking codes

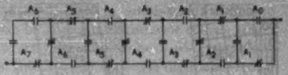

Fig. 5. Symmetric recognition network for code 01010101 and single-digit errors

cyclic coding to be used in a shaft position to digital encoder.

Karnaugh-Veitch maps have characteristics very useful in the analysis of error-protected binary coding. A 2-dimensional map can be drawn representing all combinations of a 4-bit code, with an added valuable feature: If a move is made from one square to an adjacent square in a direction parallel to the map axes, only one digit of the code changes. Fig. 3(A) illustrates this operation. Right-angle motion in any direction away from the solid circle 0101 results in the blank circles 0100, 0111, 0001, and 1101 for changes in the A_0, A_1, A_2, and A_3 digits respectively. Fig. 3(B) illustrates a similar map operation on codes at the corners. Rectilinear motion over the edge of the map is accomplished, assuming that the map is the projected surface of a toroid or a single period of a repetitive chart.

Obviously, a 4-digit map is inadequate to the task of designing a code system. The Karnaugh-Veitch map is not limited in its application to 4-digit codes. Both of the originators[4,5] of the mapping technique have proposed methods of extending the map. A very desirable extension (in the opinion of this writer) is shown in Fig. 3(C). Here the concept of equipotentiality used with the cube discussed in the preceding section is applied to combine 16 of the 4-digit figures into an 8-digit map. In Fig. 3(C), the solid circle labeled *A* represents the code 01010101 while the blank circles labeled *A* represent single-digit errors. The individual maps are canted slightly, so that a straightedge may be used to reduce the problem of identifying squares to be considered as associated between maps; this is illustrated by the dashed lines about code *A* in Fig. 3. By studying the squares connected by the dashed lines, one will note that the rules for single-digit change of code in separated maps are identical to the rules for single-digit change of code within a map. Code *B* illustrates the corner operation of single-digit errors on code 10101010. Again, the extended map operation is identical to the 4-digit map operation.

Given this principle of error recognition, one may now construct a code based on it. If single-error checking is desired, some codes will share the same single-error conditions. Code for single-error checking will be located so that at least two digits change between the codes. This corresponds to $d=2$ in the distance protection concept.[1,2]

A single-error correcting code may be designed if the single-error conditions of that code are not shared with another code. To design such a code system, then, one must locate the codes so that at least three digits change between them. This corresponds to $d=3$ in the distance protection concept.

An additional digit change between codes ($d=4$) will provide a shared second-digit error between codes. The coding will now be single-error correcting, double-error checking.

Fig. 4 will serve to illustrate the distance-protected codes; (A) shows a 4-digit single-error checking code system, and (B) a 7-digit Hamming single-error correcting code system; (C) illustrates an 8-digit Hamming single-error correcting, double-error checking code system. It should be emphasized that the mapping technique is unnecessary for designing the code systems shown in this figure. Clear rules have been stated for their formation.[1,2] (Reference 2 is a readily available book.) Fig. 4 serves as an illustration of the results desired when a distance protected coding system is designed. The mapping technique is most valuable when a system with mixed protection requirements is designed. An example to be given later will show this.

Once a code has been selected using the Karnaugh-Veitch mapping technique, a further advantage may be realized by using its contact minimization features[3,4] to select a switching function. For example, the straight minimization features may be applied to code *A* of Fig. 3 (used for single-error correction) to develop switching function:

$$\begin{aligned}F_A = {} & \bar{A}_7A_6\bar{A}_5A_4\bar{A}_3A_2\bar{A}_1+\bar{A}_7A_6\bar{A}_5A_4\bar{A}_3A_2A_0+\\ & \bar{A}_7A_6\bar{A}_5\bar{A}_3A_2\bar{A}_1A_0+\bar{A}_7A_6A_4\bar{A}_3A_2\bar{A}_1A_0+\\ & \bar{A}_7A_6\bar{A}_5A_4\bar{A}_3\bar{A}_1A_0+\bar{A}_7A_6\bar{A}_5A_4A_2\bar{A}_1A_0+\\ & \bar{A}_7\bar{A}_5A_4\bar{A}_3A_2\bar{A}_1A_0+A_6\bar{A}_5A_4\bar{A}_3A_2\bar{A}_1A_0\end{aligned}$$

Also, the symmetric function technique described by Caldwell[6] may be used to produce the contact configuration of Fig. 5.

Karnaugh-Veitch mapping is still not limited to the 8-digit examples given here. Four of the eight-digit maps may be fitted on $8^1/_2$- by-11 inch sheet of paper for 10-digit code studies. A 17- by 22-inch sheet would permit 12-digit mapping. The map cannot be compressed more than this if space is to be left for necessary notes. A larger sheet of study paper could be provided at this point to extend the map capacity, or 16 of the 12-digit sheets could be combined to provide a 16-digit chapter. The system can be continuously expanded in this fashion; however, the perseverance of most students of the code will undoubtedly be exhuasted at 12 or 16 digits. A 16-digit code map would contain 65,536 code positions and could be used to map a Hamming code with single-error correction and double-error detection for a total of 2,048 codes.

C—Specific single or double error
D—All possible errors
E—All errors beyond single error correction

ESTIMATING RELIABILITY IMPROVEMENT GAINED BY DISTANCE-PROTECTED CODING

Rice[8,9] has published very complete treatises giving means whereby single-digit error probability of a given detection system can be calculated. There are several sources[10–12] from which the probability that noise will distort a single digit of a code with a particular scheme of sampling can be deduced. Siforov,[13] in his work on codes protected by a distance between them, develops an equation which may be used with the system single-error probability, to determine the code error probability of a given distance protection. His method is applicable to a diagrammatic selection of codes similar to that shown in the preceding section; however, distance in Siforov's work allows the existence of systems in which the distance between codes d is not a whole number. Such a situation may possibly be evaluated in terms of the whole system; however, if the error probability of a single code is to be considered, a fractional distance between is hard to visualize on a coding map. This section will offer a means, compatible to a map method of code synthesis for determining the error probability of a given code.

The means considered here are based largely on a discussion of probability by Goldman.[14] The methods are valid when the code signal is to be distorted by a random disturbance, and when the probability that this distortion occurs in any one digit is the same as the probability that it occurs in any other digit.

The probability of error in any single digit must be known: p_e = average probability of error in any single code digit.

The probability of error in decoding a message will be determined: P_e = average probability that the message is decoded incorrectly.

Fig. 6 shows a group of 4-digit code maps which will be used with this discussion: (A) shows code 0111, dot A, which is distorted by noise into code 1111, circle B. This distortion implies that a single error has been made in digit A_3, so the probability that this error P_e occurs is equal to the single-digit error probability p_e. This error condition is represented by the shortest dashed path a between the circle and the dot Fig. 6(A). There are certainly many other routes by which the circle and the dot can be connected. To illustrate that these other paths are equivalent to path a, consider path b. To follow path b, distortions must occur as follows:

Digit Distorted	From	To
A_1	1	0
A_0	1	0
A_3	0	1
A_0	0	1
A_2	1	0
A_1	0	1
A_2	0	1

By examining these operations, it will be noted that the A_0, A_1, and A_2 digits each undergo two distortions, restoring them to the proper sense, and only the A_3 digit remains in error. Path b is then equivalent to path a. As only one decision is made on each digit, path b is inconsistent with the error which might occur in a single transmission and reception. In summary, the probability of any particular single-error change in a code P_e is equal to the single-digit error probability p_e, and this is indicated by the shortest path ot the adjacent square.

Fig. 6(B) shows a case in which code 0111, dot A, is distorted so that it is received as code 1101 (circle C). Here paths C and D are equally short; however, they are equivalent paths, both indicating that the A_3 and the A_1 digits must be distorted to produce code C. Since the interference was assumed random, and the digit distortion independent, the probability of this code change is evaluated as the probability that two independent events occur (a product) as follows:

$$P_e = p_e X p_e = p_e^2 \text{ for Fig. 6(B)}$$

Fig. 6(C) shows the case in which code A may become either code B or code C. Since in any one trial, only one of these changes can occur, this case involves the probability that either of two dependent events occur (a sum) as follows:

P_e = probability that code A is distorted into code B + probability that code A is distorted into code C

$$= p_e + p_e^2 \text{ for Fig. 6(C)}$$

It should be noted that this paper is primarily concerned with systems in which the single-digit error probability is less than 10^{-3}. Under this condition the square term in the foregoing equation is practically insignificant, and the probability of Fig. 6(C) conditions can be rewritten as

$$P_e = p_e + p_e^2 \approx p_e \text{ for Fig. 6(C)}$$

Fig. 6(D) considers the general case where code A can be distorted so that it will be received as any of the other codes in the system. The map of Fig. 6(D) shows all possible events which can occur in a single transmission and reception of a code, and the sum of all these probabilities is unity. Code A represents the probability that the code is transmitted and received correctly; hence, the probability that the code is distorted into any other position on the map is $P_e = 1$, the probability that the code is received without distortion.

Now, for the code to be received without distortion, each of the four digits must be received correctly. Hence

$$P_e = 1 - (1 - p_e)^4$$

$$P_e < 4p_e \text{ for Fig. 6(D)}$$

Fig. 6(E) shows the situation which must be evaluated when a coding is designed to tolerate single-digit errors, i.e., code A and its adjacent single-error squares are considered to be correct. The probability that the code is distorted into any of the circles represents the code error probability. Two evaluate this, an approximate equation, developed in the Appendix is used:

$$P_e < \frac{N!}{(N-a-1)!\,(a+1)}\, p_e^{a+1}$$

For Fig. 6(E) $N=4$, $a=1$; therefore

$$P_e < \frac{4(3)}{2}\, p_e^2 = 6p_e^2 \text{ for Fig. 6(E)}$$

Given this approximate equation, the code systems in Fig. 4 may be evaluated. The single-error checking system of Fig. 4(A) requires that two probabilities be considered. A code can be received correctly only if it has no distortion; hence the probability that the code is not received correctly, here defined as P_{ne}, will be the probability that at least a single error is made in the 4-digit code ($a=0$, $N=4$):

$P_{ne}<4p_e$ for Fig. 4(A).

Although the probability that a code in Fig. 4(A) will not be received correctly is the probability that a single digit is in error, the probability that the code will be distorted into an erroneous code requires the consideration of 2-digit errors ($N=4$, $a=1$):

$P_e<6p_e^2$ for Fig. 4(A)

For the 7-digit single-error correcting system of Fig. 4(B), the probability that the code is not received correctly is the same as the probability that an erroneous code is received. This requires a 2-digit error in the 7-digit code ($N=7$, $a=1$):

$P_e<\frac{7(6)}{2}p_e^2=21p_e^2$ for Fig. 4(B)

For a single-error checking, double-error checking code system such as that shown in Fig. 4(C), two probabilities must again be considered. First, there is the probability that the code will not be received correctly, due to 2-digit errors in the 8-digit code ($N=8$, $a=1$):

$P_{ne}<\frac{8(7)}{2}p_e^2=28p_e^2$ for Fig. 4(C)

Next there is the probability that the code will be received erroneously, due to an error of at least three digits in the 8-digit code:

$P_e<\frac{8(7)(6)}{3!}p_e^3=56p_e^3$ for Fig. 4(C)

Thus far in this consideration of code error probability, no considertion has been taken of the fact that, due to the presence of noise, the receiving decoder is not in synchronism with the received code. This consideration can be extremely important in a serial bindary coding. For example, if the means of synchronism is the addition of a single-start digit at the the beginning of a code transmission, the probability that the message is received in error (defined here as P_{em}) will be determined by two dependent error probabilities: the probability that the code digits are in error (P_e), and the probability that the synchronizing message is in error (here defined as P_{es}):

$P_{em}=P_e+P_{es}$

for codes dependent on a synchronizing message. Again, for the single-digit synchronizing message, the error probability is equal to the single-digit error probability:

$P_{em}=P_e+p_e$

for codes with a single-digit synchronizing message.

The consideration of synchronizing error probability is introduced into this section largely so that two related conclusions concerning reliable coding systems can be drawn as follows:

1. The reliability which can be secured by distance protected coding is often limited by means of synchronism.

2. If a code system is to be designed to tolerate a code error of K digits, the synchronizing message should also be designed to tolerate a synchronizing error of K digits.

An Application of Diagrammatic Techniques to Code Design

Use of the Karnaugh-Veitch map is designing a protected code system does not guarantee that an optimum coding will be produced, but it does provide considerable help in assembling mixed code systems. An example will illustrate this.

Assume that a communications link is available which can be used for code transmission with an error probability of 10^{-4}. Assume also that synchronizing means are available in the detection equipment which will provide synchronous detection with timing error probability of 10^{-7}. For this link and detector, it is desired that telemeter codes indicating discrete 10% levels from 0.0% to 100% be constructed with a probability of less than 10^{-6}, and that the received level is more than 10% of full scale different from the transmitted signal. A minimum of ten additional signals is desired, which will be used to transmit supervisory functions with an error probability of less than 10^{-6}.

To evaluate the range of protection required, substitute the specifications into the approximate equation used for Fig. 6(E) in the preceding section.

$$P_e=\frac{N!}{(N-a-1)!\,(a+1)!}p_e^{a+1}$$

and p_e 10^{-6} by specification; therefore

$$10^{-6}\geq\frac{N!}{(N-a-1)!\,(a+1)!}(10^{-4})^{a+1}$$

For $a=1$, any N less than 14 satisfies the inequality. Fourteen digits, providing a coding space for 16,384 unprotected codes, should be more than is required. Hence the system will be designed with $a=1$.

The specification for telemetering codes permits 10% errors, with no specified probability, but does require that errors larger than 10% be held to a probability of 10^{-6}. Such specification implies that the codes are distance-protected, but that codes adjacent in amplitude value may also be adjacent in the code space. Such an arrangement can be made, where one of the N possible single-digit errors of a given code may be construed as the next higher code, and another of the N possible single-digit errors may be construed as the next lower code. This construction will involve a region for each code consisting of one element of space for the true code and N-2 elements for the single-digit errors of a total of N-1 elements. As, an exception, the first and last codes can err in only one direction, and thus must have N-1 elements for single-digit errors, or a total of N elements. For maximized coding in this scheme, an N-digit code space may contain a total of $(2^N\text{-}2)/(N\text{-}1)$ such codes. A 6-digit space will provide a maximum of 12 such codes, whereas only 11 are required by the system. Fig. 7(A) shows a 6-digit map containing 11 such codes, A through K. Capital letters are used to indicate the actual coding positions. Arrows extending from these positions are used to indicate automatically correctible single-digit errors occupying the same 4-digit map as the coding position. Lower-case letters are used to indicate automatically correctible single-digit errors not on the same 4-digit map as the coding position.

This 6-digit telemetering code can be made part of an 8-digit system including the supervisory codes. The influence of the 6-digit telemetering codes on the 8-digit map is indicated in Fig. 7(B). The spaces on this expanded map, which will be occupied by the telemetering codes of Fig. 7(A), are crossed out, and additional single-error versions of the telemetering codes produced in the expanded map are indicated by lower-case letters. To preserve the required protection, it is also essential that added codes be spaced more than two digits away from the telemetering codes. Two-error versions of the telemetering codes are indicated by circles so that these spaces will not be selected as actual code locations in the expanded system.

In the remaining coding spaces, supervisory codes are selected to operate on the following principle: The desired supervisory function will be transmitted, and repeated at intervals until the distant station returns a signal verifying that it has received permissible supervisory code. The verification code ZZ is first selected in a location to be four error digits away from all other code positions, and is designed to be single-error correcting, double-error checking. The 2-digit error circles for ZZ are underlined to indicate that no code position may be located closer than two-digit errors from them. Actual supervisory codes are designed to be single-error checking only, except that where code locations permit, the 2-digit error spaces determined by the telemetering codes are used as single-error correcting spaces for the supervising codes. These supervisory codes (L to Z and ZZ) are mapped on Fig. 7(C), and combined with the telemetering codes in the complete system map on Fig. 7(D).

There are several error probabilities to be considered in the code system shown in Fig. 7(D). Telemetering codes A and K include one single-error possibility that will cause 10% error; hence the probability that they are 10% in error is 10^{-4}. Codes B through J include two such single error possibilities, and thus have a 10% error probability of 2×10^{-4}. For all the telemetering codes the probability of more than 10% is the probability that more than one digit of the 8-digit code is distorted ($N=8$, $a=1$):

$$P_e < \frac{8(7)}{2}(10^{-4})^2$$

$$P_e < 3\times10^{-7}$$

for error of 10% in codes A through K.

The supervisory codes cannot be corrected with errors in any one of six or eight of their digits; hence the probability that the code is not received is 6×10^{-4} or 8×10^{-4}. Due to the selected operation, this simply implies that these codes will have to be repeated six or eight times

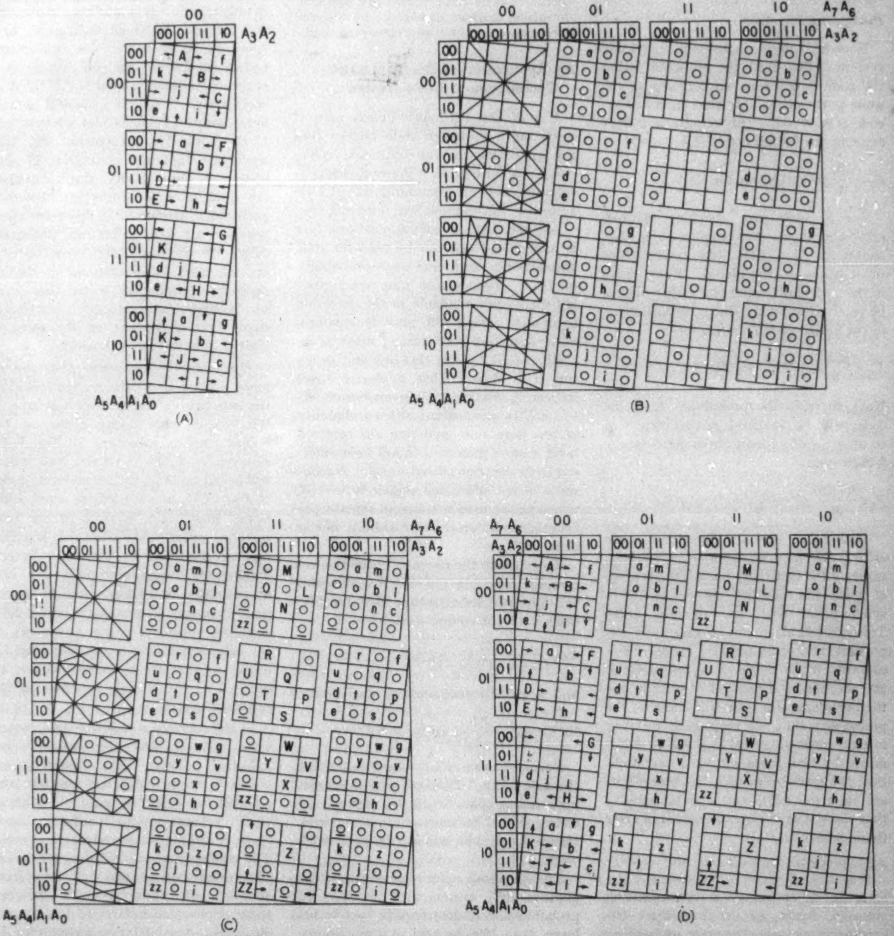

Fig. 7. Construction of a protected code system. A—Basic telemetering code. B—Effect of telemetering code on 8-digit code space. C—Supervisory code added to 8-digit code space. D—Combined telemetering and supervisory code system

per each 10,000 such transmissions. The more important probability, that a supervisory code is distorted into another valid code, requires more than one error:

$$P_e < \frac{8(7)}{2}(10^{-4})^2$$

$$P_e < 3\times 10^{-7}$$

for one supervisory code distorted into another valid code.

The verification code is single-error correcting; hence the probability that it is not received is 3×10^{-7}, as demonstrated for previous considerations permitting single errors. Due to its double-error checking feature, an error of more than two digits is required before the verification code becomes a different code, or vice versa:

$$P_e < \frac{8(7)6}{3!}(10^{-4})^3$$

$$P_e < 6\times 10^{-11}$$

for erroneous decoding in the verification codes.

The coding offered in Fig. 7(A) does not use the code space in the most efficient possible manner. Hamming offers an equation indicating that a maximum of 28 single-error correcting codes can be located in an eight-digit code space. Fig. 7(D) is, with the exception of the verification code, less than single-error correcting and does contain only 27 codes. On the other hand, the largest reported single-error construction of an 8-digit code, to the writer's knowledge,[13] contained only 19 messages. An 8-digit code space contains 256 code locations, yielding a total of 2^{256} or approximately 10^{77} functional combinations. To fit sets of these combinations perfectly is a complex problem. The diagrammatic technique shown in this report facilitates the assembly of code systems involving special protection considerations; further direction is needed to make the assembled systems as efficient as possible.

Appendix. Development of the Approximate Formula for Evaluating Error Possibility in Distance-Protected Code

When a code of an N-digit code system is transmitted, there is a finite probability that the same code will be received, or that any of the other 2^N-1 codes in the system will be received. The sum of the probability of all these possible events is unity; this may be expressed using the Bernoulli distribution law.[13]

$$1 = \sum_{R=0}^{N} C_R{}^N P_e{}^R (1-p_e)^{N-R} \qquad (1)$$

where $C_R{}^N$ is the combination of N things taken R at a time.

Note that each term of the foregoing summation states the probability that the received code will be in the group of codes located at a radius R, from the intended code (i.e., the probability of exactly R digit errors in the communication). When a coding is designed to tolerate an error of A digits, the summation in equation 1 can be divided two separate summations:

$$1 = \left[\sum_{R=0}^{a} C_R{}^N p_e{}^R (1-p_e)^{N-R}\right] + \left[\sum_{R=a+1}^{N} C_R{}^N p_e{}^R (1-p_e)^{N-R}\right] \qquad (1A)$$

The first summation represents the probability that the received code is within the specified tolerance; the second the probability that it is outside the specified tolerance. Either of these summations may be used to calculate the code error probability P_e:

$$p_e = 1 - \sum_{R=0}^{a} C_R{}^N p_e{}^R (1-p_e)^{N-R} \qquad (2)$$

or

$$P_e = \sum_{R=a+1}^{N} C_R{}^N p_e{}^R (1-p_e)^{N-R} \qquad (3)$$

Equation 3 may be further expanded:

$$P_e = \sum_{R=a+1}^{N} C_R{}^N p_e{}^R \left[\sum_{j=0}^{N-R} C_j{}^{N-R} (-p_e)^j\right] \qquad (4)$$

Equation 4 may be expanded and recollected in corresponding powers of p_e to yield

$$P_e = C_{a+1}{}^N p_e{}^{a+1} \left[\sum_{K=0}^{N-(a+1)} \frac{a+1}{a+1+K}\, C_K{}^{N-(a+1)} (-p_e)^K\right] \qquad (5)$$

The summation in equation 5 is an alternating series. The first term of the series is unity. Terms in the series will diminish from the mth term on, provided that mth term can be divided by the term immediately preceding it to yield a quotient less than unity, i.e.,

$$\frac{(a+m)(N-a+m)}{(a+m+1)m}\, p_e < 1 \qquad (6)$$

Now, the object of this investigation is the development of a simple formula approximating the exact relation given in equation 5. Such an approximation will be based on the following concepts:

1. The simplest approximation of equation 5 would involve only the first term of the summation.

2. Since error proability is stated to one significant figure, the first term of the summation will determine the error probability to sufficient accuracy provided the second term is less than 5% of the first term, i.e.,

$$\frac{(a+1)(N-a+1)}{(a+2)}\, p_e \le 0.05 \qquad (7)$$

If the conditions of equation 7 are fulfilled

$$P_e < C_{a+1}{}^N p_e{}^{a+1} \qquad (8)$$

$$P_e \approx C_{a+1}{}^N p_e{}^{a+1} \qquad (9)$$

i.e., the approximate formula given in equation 9 provides a means of calculating error probability which will be pessimistic, but less than 5% pessimistic. The following table illustrates the restrictions imposed on the use of the approximate formula by the conditions in equation 7:

Error Tolerance (a)	Maximum Code Length (N)		
	$p_e=0.01$	$p_e=0.001$	$p_e=0.0001$
0	9	99	999
1	7	75	750
2	7	67	667
3	8	63	627
4	9	63	603
5	9	62	587

SAGE Data System Considerations

NONMEMBER AIEE

A SYSTEM for the transmission of binary digital data over telephone circuits has been developed for the SAGE (semiautomatic ground environment) System of air defense. This data transmission system had to meet stringent and varied requirements for data rate, error rate, general applicability, cost, and not least importantly, reliability in the face of enemy action. The nature of these and other requirements are discussed together with some of the history of the development program which led to the present solution. A detailed description of the data-transmission system now being installed throughout the nation is given. The conclusion contains a discussion of problems still remaining and some opinions of future trends in data-transmission systems for air defense and other applications.

The Need for a Data Transmission System

In the year 1951, the "Charles Committee" was appointed by the Joint Chiefs of Staff to study the problem of air defense of the United States and to make recommendations concerning the nature of possible solutions and the means of achieving the desired goal.[1]

The future system of air defense that was proposed and subsequently accepted by the Air Force, involved the concept of a small number of centers where large-scale data processing and display machinery would be located and where instructions and control information would be generated.

Radars and other information sources would feed information into these centers now called direction centers (DCs) and the DCs would send to interceptors and other weapons the messages involved in their deployment and control.

The communication requirements for the transmission of this information were revolutionary. SAGE was planned to use the existing radars and weapons, together with many new ones, all connected to the new DC. The location of these radars was fixed by the requirements for complete air surveillance coverage and by the fundamental limitations in the performance of line-of-sight radars, and these were to be augmented to insure adequate low-altitude coverage. The locations of the DCs were largely determined by logistic factors and the paramount need for avoiding areas that might be considered prime targets for enemy attack.

Existing interceptor bases and new missile-launching bases that were to be integrated into the SAGE System were, of necessity, located on a geographic basis, to insure that an optimum distribution of weapons to protect prime targets, or expected attack routes, would be maintained.

Radio coverage for primary weapon control instructions had to match that of the radars if the weapons were not to be restricted in their operational capability. Consequently a multiplicity of such sites had to be provided, the locations being determined by the fundamental limitations of the radio equipment.

Since data were to be processed at the DC the output of the radars had necessarily to be conveyed to the DC, and with a minimum of delay. Similarly large quantities of data had to be conveyed from the DC to weapons control radio sites, and to adjacent data-processing centers to insure adequate handling of air battles which traversed the boundaries of the center control areas.

This need for transmission of automatically processed data, over long distances, between machines, in contrast to voice communications between human beings, required fundamental changes in air defense communications engineering.

Particularly applicable to the radar case, one technical solution would have been to use wide-band microwave circuits to transmit the radar video output to the DC. But this solution, apart from its prohibitive costs, would have been hopelessly inefficient because the data-processing machinery deals only with information which describes discrete radar returns. This discrete information can on the average be contained in a band-width which is approximately 1/1,000th of the video output of the radar receiver.

The more desirable system therefore involves machinery at the radar to quantize and store the processed radar data and a communication system of capacity sufficient to pass these data at no less than the average rate at which it is generated.

Outputs of the data-processing DC are originated in the form of discrete digital data. These outputs require a transmission system capable of handling at least the average rate of generation, preceded by machinery with storage to handle the transition from generation rate to average transmission rate and capable of encoding information in a form suitable for transmission.

Upon detailed examination of these and other like communication requirements, the need for a new data-transmission system became apparent. Existing data systems such as teletypewriter, were of too low a capacity and when used in multiple, too costly, and wide-band microwave video systems were unnecessarily high in capacity and very costly to install.

Historical Development

Following the recommendations of the Charles Committee, the Massachusetts Institute of Technology (MIT) formed a new laboratory to carry on research and development in the field of air defense. One of the first tasks of the Lincoln Laboratory, as it was named, was to demonstrate the principles of the proposed new semiautomatic air defense system by means of an experimental model.

Known today as the Cape Cod System, the model was set up in Eastern Massachusetts, using the Whirlwind computer in MIT's Barta Building as the basis of an air defense direction center. A number of small radars were installed at 20 to 50 miles distance from the center. Interceptor and target aircraft, based at Hanscom Air Force Base, were provided by the Air Force for the experiment.

The early data-processing machinery at these radars and the data-transmission system stemmed from work originated at the Air Force Cambridge Research

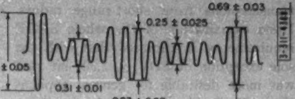

Fig. 2 (right). Idealized phone line signal

Center, at that time also located in Cambridge, Mass.

The first radar data-processing device used was called slowed down video (SDV) and it quantized the radar picture into range circles, and into azimuth sectors. The data-transmission system used a leased conventional voice telephone circuit as a transmission medium, over which was sent amplitude-modulated signals; see Figs. 1 and 2.

Since this processing and transmission was carried out in real time, the data rate was a function of the radar scan rate, and for these radars 1,600 bits/second was adequate. The inevitable small variations in radar scan rate were taken care of, not by varying the transmission rate, but by allowing variations in the number of range boxes in each discrete azimuth sector scan.

All the telephone circuits in the original Cape Cod System were made up of voice frequency facilities, and although certain of these proved too noisy and had to be changed, the data-processing and transmission systems proved adequate for the purposes of the early experiments with short-range radars.

When it was decided to enlarge the Cape Cod System, particularly to include longer range radars, a number of difficulties with the data-processing and transmission system became apparent.

To fulfill the need for an improved data-processing and -transmission system for long-range radars, a machine known as fine grain data (FGD) was developed. This device, a small computer in itself, works on entirely different principles from the SDV. In FGD, a radar echo is treated in its several separate component pulse returns and a target position determined as the weighted average of all these separate pulses. The *x* and *y* co-ordinates of this target position are determined to an accuracy much greater than with SDV and together with the time of occurrence are stored in binary form in a storage register. Two 1,300-bit circuits are used to transmit this data to the DC. In addition to handling search radar returns, identity IFF (Identification Friend or Foe) radar and height information from height radars are also stored by the FGD machine. This information is transmitted over the same two data circuits in time multiplexed form. The FGD equipment in production for SAGE use is called the Coordinate Data Transmitting Set.

In addition to search radars, other components of the Cape Cod System had need of a data-transmission system. At first height finding was carried out manually, requests and data being passed by voice to and from the center and the height-finder radars. This height system had to be improved if it was to be compatible with the performance of the rest of the system. An experimental ground-to-air data link (G/A DL) was used in the Cape Cod System for passing computer generated instructions to interceptor aircraft. The transmitter was remote from the computer and a data-transmission system was needed to convey the instructions.

The early Cape Cod experiment completely fulfilled its purpose however. It successfully demonstrated the technical feasibility and operational advantages of this revolutionary concept of an air defense system. It was instrumental in guiding the Air Force decision to proceed with a nation-wide installation. This decision demanded that the Lincoln Laboratory apply its major effort to the application of the experimental designs and equipment to a large-scale permanent installation. Not least of the many problems was that of designing and planning a new data-transmission system, to be installed on a vast scale, and with problems hitherto unknown in a nation-wide communications system.

Technical Requirements

In the consideration of requirements for the data-transmission system for SAGE, the following appeared paramount.

1. There should ideally be one "standard" system used throughout the SAGE System for all applications.
2. It should use as a transmission medium a type of circuit readily available throughout the country.
3. The incidence of errors introduced by the data-transmission system should be a minimum consistent with item 2.
4. The capacity for transmitting data (data rate) should be as high as possible consistent with items 2 and 3.

STANDARDIZATION

The general advantages here are obvious and almost need no mention. In the SAGE System there is an outstanding technical, rather than the usual logistical, advantage of standardization. A common standard of data rate and type of signal makes possible the sharing of computer input or output sections which cannot be fully utilized by one particular service.

TRANSMISSION MEDIA

It has been previously mentioned that in the early Cape Cod System conventional leased voice circuits were used for data transmission. It had been hoped that such circuits could be used throughout, but upon investigation, voice circuits were found to be quite unsuitable to meet SAGE data-transmission requirements.

First, there is no specification available to the user, of the characteristics of a voice circuit, other than it be capable, when suitably terminated, of satisfactorily transmitting intelligible speech. The data rate would be limited by the worst case of amplitude and phase distortion characteristics likely to be encountered, and furthermore, the worst case would have to be found by measurement. Second, with voice transmission, the noise on the circuit, particularly, impulse noise, is far less important than with data transmission, and there were no data available on the impulse noise characteristics, or their distribution of conventional voice circuits. Third, it is in the nature of telephone company operations that leased circuits may be changed in their make-up, or rerouted at any time to meet prevailing conditions, so that even if a voice circuit was established and found to be satisfactory for data transmission, it would not necessarily remain so indefinitely.

It became necessary then to establish a new class of circuit. Because of the need for general availability without extensive construction, the basis of the circuit had to be the same facilities used for voice transmission.

DATA RATE

It was stated earlier that 1,600 bits/second was the rate chosen for SDV transmissions from short-range radars. Upon examination of the whole SAGE requirements, it appeared that with the sole exception of SDV, a 1,300-bit rate was more desirable for general application. Used either as a single circuit, or in multiples of no more than two, all SAGE requirements could be met, including the FGD system developed for the processing of data at long-range radars. The lower bit rate was more compatible with voice circuit bandwidths and was less demanding in envelope delay equalization; also, it promised some small improvement in error rate.

ERROR RATE

In the Cape Cod System, it was observed that the noise on telephone circuits was generally of two types: bandwidth limited white noise and impulse noise. Of the two, the impulse noise contributed the bulk of the errors, since the normal signal level (0 decibels referred to milliwatts to the sync or start pulse) was well above the mean noise level. Impulse noise spikes were often of similar or greater magnitude than the level of data pulses.

A noise impulse, after being shaped by the circuit, often appeared as a false bit of data or might cancel a real bit of data, depending upon its time of occurrence and its phase relationship. If the error rate was to be minimized, then attention would need to be focused on reduction of impulse noise, rather than on improvement of signal/white noise ratio.

In early 1954 a committee was formed to specify the characteristics required for a data circuit to meet the requirements in the preceding.

In Appendix I the specifications are given that the committee decided upon for a data circuit, which appeared to satisfy all requirements. The characteristics of the signal to be sent over this circuit were also defined and are given in Appendix II and Figs. 1 and 2.

A number of data circuits were provided to replace the voice circuits in use in the Cape Cod System and the anticipated improvement in performance over the conventional voice circuits was immediately apparent.

The terminal devices, modulators, and demodulators that were used in the Lincoln data-transmission system were called digital data transmitters (DDTs) and digital data receivers (DDRs) respectively. The input to the DDT consisted of unidirectional pulses for sync and data signals and of a continuous sine wave for timing. The output of the DDR consisted of unidirectional pulses for all three signals, sync, data, and timing. The amplitude and duration of these input and output pulses were chosen to make them directly applicable to the digital logic circuits of the data-processing machinery.

The "on line" signal transmitted by the DDT Fig. 2, Appendix II, utilized a basic carrier onto which the signal waveform was modulated.

This particular design of DDTs and DDRs evolved directly from experience with the specific telephone circuits used in the Cape Cod System and with loop circuits in the laboratory for test purposes.

With increasing experience gained with a larger variety of circuits, came the further realization that it was impractical to consider the DDT, DDR, and telephone circuit as separate entities, but because of the many types of telephone circuits and continued improvement in telephone facilities, they should be considered as a complete system providing digital data transmission between two points.

Although Lincoln designs of DDTs and DDRs appeared to be adequate, it was recognized that separate ownership of the terminal equipment would inhibit changes which could utilize important inventions in the field of telephone communications. In addition, requirements had been stated by the Air Force for rapid restoration of data circuits in the event of failure. The optimum solution required that trouble sensing devices and automatic switching be included as part of the terminal DDR equipment. Further, from the point of view of maintenance, it was considered essential that test signals and devices be included which would check the data circuits as well as the DDTs and DDRs.

Accordingly, agreements were reached on the characteristics of a complete data service which would include both terminal equipment and transmission media.[2,3]

A standard signal specification was agreed on, such that the synchronization, data, and timing signals are all delivered to a Data Service as a standard sine wave or dipulses and the new DDT transmits these signals in a manner optimum for transmission over the particular facility which is being employed. At the receiving end, the new DDR converts the complex on-line signal into three standard sine wave or dipulse signals for delivery of sync, data, and timing information to the user.

The specifications for input signals to DDTs and output signals from DDRs are given in Figs. 3 and 4. These differ considerably from those used with the Lincoln DDTs and DDRs. The d-c levels and high-amplitude narrow pulses used in the Lincoln system precluded the possibility of having DDT or DDR equipment remotely located from the data sources or data receiving equipment except when interconnected by coaxial cable. In addition, equalization might have been required. Further, the necessary switching of circuits for restoration, or patching to other input or output equipment was complicated enormously with the Lincoln-type wave forms.

In order to obviate these difficulties, input and output signal wave forms have been established for the Digital Data Service, which allow transmission via regular telephone facilities and house cables, and which allow switching and patching via conventional equipment. These input and output signals have been adopted as standard for the SAGE System.

The specified error rate for the Data Service is identical to that specified in Appendix I for data circuit, i.e., not more than one impulse noise spike, (or bit error), per minute. This, at a 1,300 bit/second data rate, is approximately 1 in 10^5 bits. It has been long recognized that this particular specification is unsatisfactory because it does not specify distribution either on the circuit in question or in relation to other data circuits. Telephone circuit noise is not generally a purely random phenomenon but often occurs in bursts, in which a large number of errors is concentrated in short time intervals; the effect of this noise on system operations, is more dependent on its time distribution than on its frequency of occurrence. It is not, therefore, sufficient to specify only a random rate of permissible errors; the length of the intervals during which these normal rates may be exceeded and the minimum time between these intervals must be considered.

The effect of errors on the SAGE System can only be considered for a whole class of like inputs or outputs, and not on an individual circuit basis. It has been calculated that for all the gap filler radar inputs to an average center, a random error rate of one per 10^5 bits would result in a 1% loss of automatic initial pick-up capacity. This is well within the system capability but if the total errors from gap filler circuits were distributed such that one in 10^4 bits were in error for a given period, then some 10% of the initial automatic pick-up capacity of the computer might be wasted during that time. Similar calculations have been made for other classes of inputs and outputs which

serve to amplify the need for knowledge of distribution of errors. To help fulfill this need, laboratory and field programs for error measurement on various types and length of data circuits are being carried on.

In any consideration of data-transmission errors in the SAGE System, a factor of great importance is whether the errors are detected or undetected. An erroneous word which is detected by some device at the receiving terminal of the data-transmission system, can be rejected before it is inserted into the data processing machinery. An undetected word error is fed into the input machinery and consequently has to be processed in order to reveal its false character. In both cases the original word is lost, but in the second case, valuable processing capacity is wasted also. It is then important that error detecting devices be included as part of the transmission and processing systems; some types are already in general use, and others undergoing laboratory and field tests. In general use throughout the SAGE System are simple and interleaved parity checks.

In the simple case, every 16 bits are parity checked; that is, an additional mark or space, as appropriate, is added to the word such that the total of marks adds up to an odd number. Any single false mark or lost mark will disturb the count, and the word can thus be recognized as being in error. Early conjectures indicated that a significant number of errors would occur in adjacent bits in the same transmission. Such errors are normally undetected by simple parity checks. As a protection against such types of consecutive errors in any word, individual words were interleaved.

In an interleaved transmission, the bits in each of a number of words are separated so that the first transmitted sequence consists of all the number 1 bits on n words, the second sequence all the number 2 bits, down to the $n+1$ sequence, which contains all the parity bits. If a, b, c through n are words, and subscripts represent bit order in each word, the sequence is thus:

1st sequence—$a_1, b_1, c_1 \ldots n_1$
2nd sequence—$a_2, b_2, c_2 \ldots n_2$
3rd sequence—$a_3, b_3, c_3 \ldots n_3$
nth sequence—$a_n, b_n, c_n \ldots n_n$
$n+1$ sequence—$a_{\text{parity}}, b_{\text{parity}}, c_{\text{parity}}$ through n_{parity}

Experience will show whether simple or interleaved words are less liable to error. Whether simple or interleaved parity checks are superior in performance is of course a function of the distribution of errors, and until more data are available, no conclusions can be drawn.

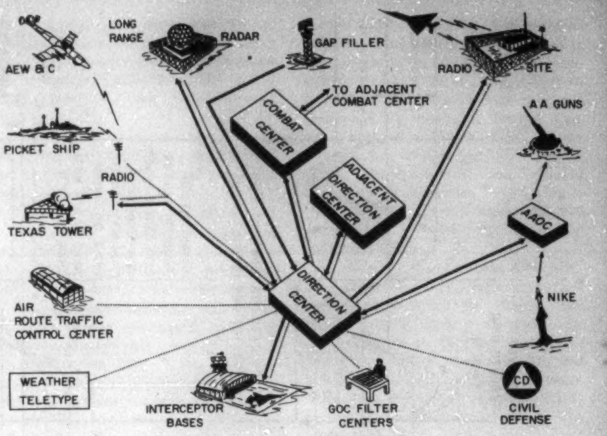

Fig. 5. Typical SAGE sector

—— Data circuits . . . . Other circuits

All data inputs and outputs are parity checked with the sole exception of the gap filler SDV inputs, to which they are not applicable.

System Composition

An elaborate communications network[4] is required to connect the computer[5] to all of the data sources and to the weapons being used for air defense. The basic communication plan developed for the SAGE System combines the technical requirements of the system designer with the operational requirements of the Air Force. One of the most important is optimum reliability at a minimum cost consistent with these requirements. Installations remote from the centralized electronic digital computer that utilize data circuits can be grouped in the following four categories:

1. Surveillance sources (input information).
2. Weapons sites and surveillance control (output information).
3. Similar adjacent computers (input and output cross-telling).
4. Computers at higher Air Defense Command levels (input and output cross-telling).

Fig. 5 illustrates the components of a typical SAGE sector. The heavy interconnecting lines represent the data circuits required between a direction center and other installations. The light lines indicate the remaining voice and teletypewriter circuits that make up the balance of the communication network.

SURVEILLANCE SOURCES (INPUT INFORMATION)

Currently there are five types of surveillance input sources to the centralized computer that employ data circuits. A brief description follows:

1. The largest volume of such input information is received by the computer from a long-range (heavy) radar installation. At a long-range radar site, three kinds of equipment are used to obtain track information. First is the long range surveillance radar. From this, radar returns are obtained from all aircraft within range. Second is the IFF which provides unique beacon assist returns from all friendly aircraft carrying such equipment. This permits tracking aircraft from which there would be an insufficient skin return. Third is the height finder radar. Height finders are necessary because most surveillance radars do not give a target altitude reading. In addition, this unit of equipment provides information that helps in estimating the size of a flight, that is, the number of airplanes in a single flight that are so closely grouped they appear as a single return on a surveillance radar. At this site, information from these three equipments is fed simultaneously into another smaller computer known as the Coordinate Data Transmitting Set. The volume of output information from this set under full load conditions exceeds the capacity of a single 1,300 bit/second data circuit. Consequently, two such circuits are required between this location and the DC.

2. To fill in the low altitude areas not covered by the long range radars, small

gap filler radars are employed. These gap filler radars are automatic, unattended equipments which are connected to the computer by a direct data circuit. This is the only application in which SDV or the 1,600 bit/second data service is employed.

3. Man-made islands known as Texas Towers are anchored to ocean shoals off the Atlantic seaboard. They are so named because of their resemblance to oil derrick platforms used in the Gulf of Mexico. Installations of these towers are similar to those of a long range radar site. Input information to the computer is the same as described in item 1 of this section.

4. Certain long-range radars are so located that their area of surveillance provides coverage not only in the sector in which they are located, but also a considerable and useful coverage in one or more adjacent sectors. When this feature is utilized, the site is called an overlap heavy radar. Since the same considerations apply as when the site functions as only a long range radar site, two additional data circuits are required for direct connection to the input of the computer at each adjacent DC involved.

5. There are two types of guided missile weapons bases that employ data circuits connecting directly to the input of the computer.

    a. The first is the Air Force Bomarc squadron. A single data circuit is employed here to pass missile status information to the DC for automatic insertion into the computer.

    b. The second is from the Army Anti-Aircraft Operations Center (AAOC). This installation controls the NIKE missile. As for the Bomarc squadron, a single data circuit is employed to transmit status information.

These are not the only input sources that are utilized in the system. They are, however, the only ones that currently employ data circuits as direct input information to the centralized computer as shown on Fig. 5. Input information from other sources is transmitted by voice or teletypewriter to a manual input room. At this location, the information is transferred to punch cards, and then fed into the computer. It can be anticipated that the future will see more of the manual input information converted to automatic input information employing some type of data service.

Weapons Sites and Surveillance Control (Output Information)

Besides computers, there are currently four types of data using installations that require output information. Three of these involve control of defense weapons while the fourth deals with surveillance. Following is a brief description:

1. The G/A DL[6] employs frequency division radio equipment. When connected by data circuits from the proper output section of the computer, this equipment will permit the automatic transmittal of flight instructions to manned interceptors. All of the complex co-ordinates and numerical readings required to vector the interceptor pilot to the enemy target are handled automatically. The data link minimized human intervention in routine actions. Because of the design of the DL equipment and the volume of information handled, two data circuits from the output of the computer to the DL ground equipment are required. The principle of interleaving, described earlier, is used to integrate the computer messages for transmission.

2. Control signals for the Air Force Bomarc missile will also be transmitted from G/A DL sites suitably located for this purpose. Although this represents control and flight instructions to a guided missile, rather than to a manned interceptor, the same considerations as discussed in the preceding apply.

3. The inclusion of AAOC in the SAGE complex presented a challenging situation in the integration of an Army-designed weapons system with an Air Force-designed air defense system. The Army Missile Master system for control of the NIKE missile was developed on the basis of receiving data at the rate of 750 bits/second. Since the SAGE computer, however, had not been designed with a 750 bit/second output section, some compromise was necessary. In order to make the two systems compatible, equipment to convert from 1,300 to 750 bit/second rate has been designed.

4. The last type of output data circuit required is to connect the computer to height-finder radars. Here a single circuit is employed for transmitting height request orders to each height-finder in the sector. By this means, height information is obtained on a semiautomatic basis.

As with input information, there are other users of information developed by the computer and personnel within the DC as indicated in Fig. 5. These users do not receive their information automatically from output sections of the computer. Rather this is done manually by voice and teletypewriter circuits. It can be anticipated that in the future more of this information will be handled on an automatic basis. Even at present, transmission over certain teletypewriter circuits is accomplished directly from output sections of the computer rather than by the more conventional means.

Similar Adjacent Computers (Input and Output Cross-Telling

Since an air battle may progress through more than one sector before being brought to a final conclusion, means for handing over control from one DC to another must be provided. For this purpose, automatic cross-telling of tracks between a computer and all adjacent computers is required. A single data circuit is provided for this purpose. Since there is a requirement for information flow in both directions, a total of two such circuits is needed between two adjacent DC.

Computers at Higher Air Defense Command Levels (Input and Output Cross-Telling)

The Combat Center (CC) contains a high-speed electronic digital computer designed to perform its specific functions in the air defense system. From each of the DC computers in the division's area of command, the CC computer receives the sector's air situation summary and combines all of these into an over-all picture for the entire air division. A single data circuit from each DC to the CC is needed for this purpose. With such an over-all summarized air picture available at the CC, command personnel are in a position to arrange for redeployment of defensive weapons as required by the battle situation. Similarly, a data circuit from the CC back to each of its DCs is required.

In all cases, each CC building is constructed adjacent to a DC building. The distance between the two computers is relatively short. The DC computer at such a location transmits the timing, sync and a data sine wave or dipulses directly over house cables to the CC computer.

Just as there is a need for data circuits in both directions of transmission between adjacent DCs, there is a corresponding need between adjacent CCs. Here, two single data circuits (one for each direction) are required to transmit the summary of the air situation and weapon status.

Operational Requirements

In May 1954 Headquarters, Air Defense Command (ADC) made known their operational requirements for restoration of circuits to the Western Electric Company, Air Defense Engineering Service (ADES) Organization. Two different desired restoration times under two conditions of air defense, namely, a "normal" and an "alert status," were presented. Certain critical circuits in a sector required almost immediate restoration while others permitted a slower restoration.

These requirements covered all of the various types of circuits required in the elaborate communications network. The following 3-part discussion will cover only the data circuits and will describe the plan evolved to meet ADC's operational requirements for this group of circuits.

Restoration

One of the most important requirements for SAGE circuits is optimum reliability at a minimum cost consistent with ADC's operational requirements. Failure of circuits can occur due to such causes as equipment troubles, human error or acts of nature. In addition, it is essential that the SAGE System capabilities be maintained even under adverse conditions of partial communication failure due to sabotage, bomb damage or other acts of war.

Three methods were considered for the restoration of service on circuits which have failed. The faster the restoration requirement, the more expensive the cost of the method employed.

1. The first method is lowest in cost and longest in time. This involves providing only a single circuit between two points. When a failure occurs, restoration is made by the usual circuit repair methods. Depending on the type of trouble and the particular circuit or facility involved, restoration may be made in minutes or may require hours. Only two types of data circuits rely on this method of restoration.

2. The second method considered was the employment of engineered military circuits (EMCs). By this method, if the single circuit described previously is considered as the regular circuit, where the operational needs are of an extremely vital nature, a second or alternate circuit can be provided. Two such circuits (regular and alternate) are termed a "dual facility." An EMC is not required on a full-time basis, but is established by the commercial communication companies at the request of the military services and is paid for only for the period of time that it is ordered for service. Since the Air Force has been the only user of this grade of data service, the communication companies do not have EMC data-type circuits available as would be true for voice and teletypewriter circuits. Various plans employing an alternate use concept of voice and data were considered that would meet the operational needs of the Air Force and still provide the economy of EMCs. Because of the operational complexity of even the simplest of these plans, the ADC reluctantly decided that this method was not feasible for data circuits. However, EMCs are utilized for the other types of communication services.

3. The third method is basically the same as the one just described, except that the alternate circuit is ordered on a full-time basis as is the regular circuit. When such a dual facility is provided, a decision is necessary to determine whether the transfer of service from the regular (when failure occurs) to the alternate should be accomplished manually or automatically. Operational requirements, together with the number of circuits involved, dictated that this be done automatically. Since a data circuit is a one-way transmitting facility, the problem is simplified. By parallel or bridge-feeding the sending end of both circuits, each circuit will be energized simultaneously with the same information. Fig. 6 shows the requirements established to meet this method of operation. A trouble detector is located at the receiving end of each of the two circuits. Normally the data using equipment takes service from the regular circuit. When trouble occurs on this circuit, the detector actuates the switch or relay to transfer to the alternate circuit. In the event both circuits are in trouble simultaneously, no transfer occurs. Visual and audible alarms are specified as requirements along with a manual control to provide an override feature.

Leased communication facilities are provided on a dual basis consistent with other components of the system.

Route Selection

Where dual facilities are specified, it would be unwise to provide both the regular and alternate circuits over the same geographic route and type of facility. Dual circuits on the same route would offer little or no protection against the ravages of nature or acts of war. Even without the provision of dual circuits, a measure of protection against outages from any cause would be achieved by dividing regular circuits among two or more routes.

Because of these considerations, where dual circuits are specified, at least two routes are also included as part of the requirement. These are to be completely separated. Routes have been selected which avoid major target areas.

In general, no attempt is made to specify the basic type or types of facility that should be utilized on each of the two routes. The communication companies are aware of the fact, however, that a diversification by types of facilities between routes is desirable in cases where this will improve reliability. As an example, underground facilities are less likely to suffer damage from a hurricane than say an open wire or an aerial cable line. On the other hand microwave radio relay facilities may be easier to protect against acts of sabotage than the open wire or aerial cable type of telephone plant.

Special Cases

For a majority of the types of remote locations that receive output information from the SAGE computer, the full 1,300-bit capacity of the data circuit is not required, or the same information is used at more than one location. This permits using a single computer output section to feed information to more than one location. If different messages are required at different locations, appropriate addresses are inserted in the messages to permit the required location to accept only the needed information. In these cases, a number of points such as adjacent DCs are fed from this one output section. Economies in charges for such leased circuits can be achieved if, instead of ordering individual point-to-point circuits from the transmitting DC, a multipoint circuit is ordered.

In addition, data circuits from a long range radar that serves as an overlap heavy radar are provided to the parent

DC as well as to adjacent DCs on a multipoint basis.

Where data circuits are ordered on a multipoint basis, a requirement has been stipulated that the bridging arrangements provided be such that trouble on one leg of the bridge cannot feed back into other working legs. Even with this safeguard, one might question whether employing a multipoint arrangement was logical with all of the emphasis that has been placed on reliability and circuit restoration. If the first bridge point were 50 miles from the originating DC, any failure in this first 50-mile section would affect the service to all receiving points.

However, in the common route portion of circuit facilities, the point-to-point arrangement is just as vulnerable to failure due to acts of war as the multipoint arrangement. In some cases, the same is true with regard to outages occasioned by day-to-day maintenance troubles, as in Fig. 7.

Development, engineering, manufacture, installation, test, and evaluation are all going on simultaneously due to the urgency of the SAGE program. Advancement in the state-of-the-art imposes changing requirements on the data circuits. A case in point is that of G/A DL communications.

The frequency division G/A DL system, previously mentioned, has been designated by the Air Force as an interim system, and is to be replaced by a time division G/A DL system. In the frequency division system, every ground radio transmitter in a sector is simultaneously transmitting the data generated by the computer. In the time division system, however, only one transmitter will be radiating at any given time.

Technical requirements of this new system are such that a new limit will be imposed on the data circuits which will feed the time division G/A DL equipment. Because of the composition of the message format and to avoid overlapping as the radio transmitters are keyed sequentially, there is a requirement that computer-generated messages should arrive at all sites over all circuits and routes almost simultaneously. Since the different circuits will have varying lengths and will consist of different kinds of facilities with differing velocities of propagation, there will be a variation in transmission speeds. A 2-millisecond differential limit has been established for these circuits. As a consequence, differential delay equalization will be needed to meet this 2-millisecond requirement. Multipointing is feasible for both the frequency and time division system.

Conclusions

While considerable progress has been made in establishing and meeting the needs for SAGE data system requirements, it should not be assumed that all work has been completed in this field. The following conclusions are reached:

1. Data transmission requirements for SAGE have been prescribed. These combine the technical requirements of the system designer with the operational requirements of the Air Force. The important requirement of optimum reliability at a minimum cost has been carefully considered. A workable method of meeting these requirements is available.

2. More experience is needed to determine ultimate data transmission standards for optimum bit rates and error rate per channel. Refinements are needed since the present data system integration is not optimum in this regard as indicated by the difference in bit rate for SAGE and an AAOC.

3. A continuing conversion of inputs and outputs from manual to automatic is to be expected.

4. New surveillance and weapons systems can be expected which will need to be integrated with SAGE. The data transmission requirements for these new systems are not yet known.

5. Improved techniques arising from this military application will find application also for industrial users.

Appendix I. Data Circuit Characteristics

1. *General.* The circuit shall be suitable for unidirectional transmission only.

2. *Impedance.* The circuit shall be designed to work into terminal impedances of 600 ohms, resistive.

3. *Net Loss.* The 1,000-cycle net loss of the circuit shall be 20 db (decibels) with not more than ±1.0 db daily variation and ±4.0 db seasonal variation.

   a. The net loss in the preceding is effective between the customers' sending and receiving equipment. For circuit layout purposes normal telephotograph practices will apply.

4. *Frequency Response.* The circuit shall transmit all frequencies between 500 and 2,500 cycles with not more than ±3 db variation over this band. Between 300 and 500 cycles the response shall not exceed the 500-cycle response by more than 2 db. Between 2,500 and 3,000 cycles the response shall not exceed the 2,500-cycle response by more than 2 db.

5. *Envelope Delay.* The total difference in envelope delay between any two frequencies in the band from 1,000 to 2,500 cycles shall not exceed 500 microseconds (μsec).

   a. On data circuits used for multiplexed transmission in groups of two or three, and specifically ordered as such, the difference in envelope delay at 2,000 cycles between any two circuits in the group shall not exceed 300 μsec, with not more than +50 μsec variation from this figure in long-time variation.

6. *Noise.* The weighted noise level, measured as below, shall not exceed 40 db below the synchronizing signal level. The number of impulse noise peaks which equal or exceed 18 db below the synchronizing signal level shall not exceed 1 per minute.

   a. The noise weighting characteristic used above shall be the standard *F1A* plus the telephotograph network, corresponding to present telephotograph practices.

   b. The data circuits will be terminated in well-balanced coils and all normal precautions will be observed as to circuit unbalances, etc. The customers' equipment shall also include a well-balanced input transformer with no connections to ground on the line side of the transformer.

7. *Modulation.* The voltage sum of the modulation components of the signal generated in the data circuit due to 60, 120, and 180 cycles shall not exceed 30 db below the synchronizing signal level.

8. *Transmitting Level.* The maximum signal level fed to the data circuit at the transmitting end shall not exceed the peak-to-peak voltage of 0 dbm into 600 ohms. In accordance with item 3 of the foregoing, the signal voltage at the receiving end of the data circuit will be 20 db below this.

Appendix II. Signal Characteristics

Four kinds of data are transmitted as follows: a sync pulse, a frame pulse, timing pulses, and data pulses. The modulation is applied as a square wave of varying amplitude (see Fig. 1) on a carrier of 2,000 cycles, or of 1,950 cycles.

If any one piece of data is defined as a bit, then the bit rate is 1,600 pulses per second or 1,300 pulses per second or the duration of a bit is 1/1,600 second (625 μsec) or 1/1,300 second.

The form of a typical signal with relative amplitudes and tolerances is shown in Fig. 2.

It will be seen that if the sync pulse has a peak amplitude of 1.0, then the unmodulated carrier has an amplitude of 0.25. The carrier plus superimposed timing has an amplitude of 0.31. The carrier plus a data pulse has an amplitude of 0.63, and the carrier plus data plus timing has an amplitude of 0.69. The frame sync pulse has an amplitude of 1.0 and occurs in the time interval immediately following the sync pulse.

A signal which is greater than 0.44 in amplitude is construed as a data pulse. A signal greater in amplitude than 0.75 is construed as a sync or frame sync pulse.

Synopsis. Accurate timing waves for the transmission and decoding of a kilobit per second data signal are generated by the use of tuning fork resonators in a flywheel-type of synchronization circuit. Accuracy of the derived timing wave is good enough that the timing jitter makes a negligible increase in the error rate. Synchronization is established in about 20 milliseconds prior to sending data.

DIGITAL data transmission depends upon the transmission of time variable electric waves. Usually, the signal takes the form of a succession of pulses of prearranged duration. The data are recovered with the aid of a clock of some sort. If the transmission speed is very low compared to the bandwidth of the medium, the clock may be so simple that its presence is not recognized. If maximum speed is to be attained, transmitting and receiving clocks must maintain synchronism with error negligible compared to the duration of a pulse.

A clock is a device which marks periods of time which should all be equal. The operation of a clock can be specified by the period T of its marks and by a smaller time t_0 specifying the displacement of one mark from a reference, or zero, time. Two clocks, standing side by side, are synchronous if these two parameters for one clock are the same as those for the second. A transmitting clock controls the length and spacing of information bearing pulses. The minimum spacing of pulses is a useful unit of time and will be called a "tick." A receiving clock is used to analyze or decode the received sequence of pulses. When these clocks are separated by a significant distance, the idea of synchronism needs to be extended slightly. The electric signal is delayed in transmission. Usually, there is some dispersion or phase distortion in transmission. It is convenient to consider the clocks synchronous when the receiving clock has the same period T as has the transmitting clock but lags by a time equal to the time of flight or envelope delay of the most significant portions of the message wave. This relation can be established by sending and receiving some prearranged starting signal. This operation permits setting the zero of the receiving clock to agree, within some tolerance, with that of the transmitting clock. When this is done, the delay in transmission is not important provided it does not change after the starting signal is sent.

The teletypewriter code is sent by the aid of a simple timing method: start-stop synchronization. The advantages of this well-known system are simplicity and capability of sending short messages (5 bits long) at irregular intervals. Its disadvantages are that it uses about 30% of the time on the transmission line for establishing synchronism, and that each "setting" of the receiving clock depends on a single transition from marking to spacing and so may suffer substantial error.

If the typical message is much longer than 5 bits, a starting signal can last for many ticks without adding greatly to the total transmission time. The error in setting the receiving clock tends to vary inversely with the duration of the starting signal, which is usually a sequence of alternate marks and spaces. The message wave also contains some information about the transmitting clock. This can be used to improve the zero setting and to adjust the period of the receiving clock.

Requisite of a Good Synchronization System

A good system of synchronization will use a minimum time before the beginning of a message for setting the receiving clock to agree with the transmitting clock. It will be able to bridge any probable run of marks or spaces in transmission. It will not depend upon any one or small number of transitions for establishing its timing, but will average the effects of many.

In transmission of random data, there is no restriction on the length of run of marks or spaces but a practical upper limit is about 50. However, some plans envision back and forth receive and confirm operation. In this case, the receiving clock should remain in step for about one second with no received signal.

Methods of Synchronization

Two general methods of synchronization exist. An oscillator having nearly the correct frequency can be used as the receiving clock. The zero set can be accomplished by adjusting a phase shifter or delay line under control of the start signal. An automatic frequency control system can be set up to compare the time of pulses from the receiving clock with the time of receiving corresponding pulses from the transmitter and to adjust the frequency of the receiving clock to minimize the average discrepancy. Alternatively, a narrow-band filter or resonator may be driven by pulses derived from the received wave to serve as the receiving clock. This second system is often called flywheel synchronization. Either method tends to average the effects of many received message pulses in order to determine suitable values of period T and zero set t_0. It is believed that the controlled oscillator should give superior results, but the flywheel system is very good and is simpler.

FLYWHEEL SYNCHRONIZATION

If the information is transmitted by rectangular pulses of duration T sent or

Paper 58-300, recommended by the AIEE Data Communication Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted April 3, 1958; made available for printing July 24, 1958.

J. O. Edson and M. A. Flavin are with the Bell Telephone Laboratories, Inc., Murray Hill, N. J., and A. D. Perry, formerly with Bell Telephone Laboratories, Inc., is now with the General Electric Company, Ithaca, N. Y.

suppressed at regular intervals T, then the spectrum of these pulses contains no lines at the bit rate or its harmonics. Limiting the received signal produces a rectangular wave which tends to be positive for one half the time as does noise. It differs from noise in that the transitions from plus to minus or from minus to plus occur only at certain permitted times at intervals T. A differentiating network can produce short positive and negative pulses at these transition instants. The spectrum of either the positive or the negative pulses comprises a noise-like continuum and lines at $1/T$ and its harmonics. A full-wave rectifier serves to invert the negative or positive pulses, depending on design, and to accentuate the lines compared to the noise-like background. A high Q resonator can select the fundamental line or a harmonic and further suppress the background noise. If the resonator operates on a harmonic of $1/T$, it must be followed by a divider chain which produces the bit frequency.

When the message has been transmitted over a medium having minimum bandwidth and some delay distortion, the pulses from the differentiator tend to be advanced or retarded relative to the instants at which they would otherwise have occurred. Line noise aggravates this effect. This results in phase modulation of the frequency $1/T$. A high Q resonator averages the effects of many pulses and thus reduces the phase modulation. In addition, it can ring for many periods without excitation, bridging long runs with no transitions. The disadvantages of high selectivity are that better frequency accuracy is required and that it is more difficult to build up the oscillation quickly at the beginning of a message. The start problem has been solved by driving the resonator with pulses of about eight times normal amplitude for about 20 milliseconds. This brings the response up to a sufficient amplitude to supply satisfactory timing pulses.

CHOICE OF A RESONATOR

The resonators in a flywheel synchronization system must meet a number of severe requirements. The receiving resonator is particularly critical. It must have high Q, good frequency stability, a large ratio of bandwidth to drift of resonant frequency, and small undesired transmission. A resonator meeting the receiver requirements will be adequate for the transmitter as well.

The need for high Q has been mentioned in the previous section. A Q of several hundred to several thousand will provide both sufficient averaging time and adequate performance in bridging gaps of several hundred to several thousand ticks.

During a gap the receiving resonator rings at its natural frequency. If this frequency differs from the selected harmonic of the transmitting bit rate, timing errors will accumulate. If the error at the end of a 100-tick gap is to be less than 1/10 tick (which is not excellent performance), the frequency error may be no more than 0.1%. Assigning half the tolerance to the receiver gives accuracy requirement of 0.05%, or 500 parts per million (ppm). For 1/10 tick error at the end of a 1,000-tick gap the tolerance is 50 ppm.

Except during gaps, it is convenient to think of the receiving resonator as selecting the line in the spectrum of its input signal at the nth harmonic of the bit rate and rejecting the remainder of the spectrum, particularly the noise components. Any deviation of the resonator frequency f_r from the frequency of this line nf_b introduces a phase displacement in the resonator output and a corresponding phase change in the recovered timing wave. If the system is initially set on tune and then drifts, the phase error in the recovered timing wave, for small drifts, is:

$$\Delta\varphi = \frac{1}{n} \tan^{-1} 2Q\left(\frac{\Delta f_b}{f_b} - \frac{\Delta f_r}{f_r}\right)$$

The possibility of limiting this error by increasing n is limited by the presence of jitter in the received transitions. The resonator measures jitter in units of its natural period, and thus sees an effective jitter which increases directly with n. Since the strength of the desired line in the resonator input spectrum falls off and the noise level increases, as the effective jitter increases, operation at large n carries a signal-to-noise penalty. Values of n greater than one put a premium on good signal-to-noise ratio because a missed or added zero-crossing in the resonator output throws the divider chain out of step. Finally, large values of n lead to difficulty in getting the divider chain in step initially.

The disadvantages of large n are great enough that $n = 1$ would be the preferred value if suitable resonators were available. Values greater than two impose impractically severe limitations on jitter. If we require that detuning errors introduce a timing error of at most a tenth of an interval, the ratio of bandwidth to frequency error (for each resonator) must be greater than 13 (or 6.8) for $n = 1$ (or 2). With a Q of 500, the corresponding frequency stabilities are 155 and 300 ppm.

Q's of several hundred are not easily obtained with passive inductance-capacitance circuits in the 1 kilocycle region. While it is possible that active Q-multiplier circuits could be used, stabilities of a few hundred parts per million are difficult enough to achieve with passive elements that the added drifts of active elements make the approach unattractive.

One may achieve excellent stability with resonators involving mechanical motion—tuning forks and crystals. With these elements the frequency accuracy is certainly sufficient for bridging 100-tick gaps. The Q's, however, will be 5 to 10,000 for forks and 50,000 or more for crystals. Even with $n = 2$ (which was selected for the experimental models) required stabilities are of the order of 20 ppm for forks and 3 ppm or less for crystals. Since these tolerances are severe, it is desirable to look for ways around them.

Two alternate approaches are available. One may reduce the Q of the circuit by applying negative feedback around the resonator, or he may increase the bandwidth by translating the input signal up in frequency and the output down by modulation techniques. Both techniques have been used in the past in less critical applications. Negative feedback raises the level of undesired transmission and runs into trouble with secondary resonances of the vibrating system. Modulation techniques demand the matching of two resonators so that the difference of their frequencies is the desired transmission frequency. Neither method is simple.

A single thermostated precision audio-frequency quartz crystal might provide an adequate ratio of bandwidth to frequency drift. It would, however, be bulky, expensive, and subject to breakage in normal handling. At least the thermostating and handling problems may be eliminated by using a precision tuning fork.

Because the most common application of tuning forks is in frequency control of oscillators, not all manufacturers supply units suitable for use as filters. There are two common defects: secondary resonances which introduce undesired peaks in the transmission curves, and insufficient isolation between the input and output, which produces an undesirably large nonresonant coupling. Forks supplied by Times Facsimile Corporation have been found free of spurious transmission peaks. The standard models provide about 30 decibels more resonant than nonresonant transmission, which is usable but definitely less than one would like.

These forks have a temperature coeffi-

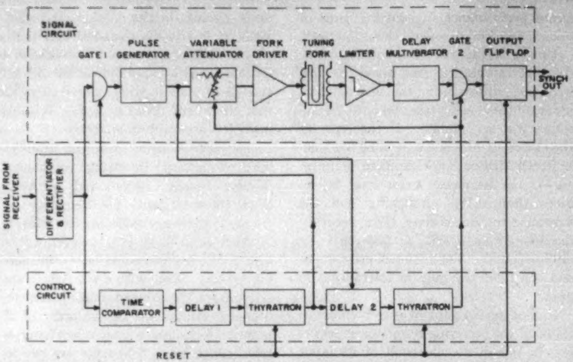

Fig. 1. Synchronization recovery system

cient of less than 0.2 ppm/degree centigrade in the 10–65 degrees centigrade range, which is acceptable. The aging rate claimed is less than 5 ppm per year. This rate is acceptable for experimental work. In field service, aging would be corrected by periodic retuning, which is accomplished by adjusting the drive and hence the amplitude of oscillation. This in turn changes the resonant frequency, by about 75-90 ppm for a change in drive from one volt to 5 volts. This nonlinearity in fork characteristics is useful in the transmitter since it provides a simple means of adjusting the clock frequency, but in the receiver it leads to a variation in output phase when the average number of received transitions per second varies. Because of the long averaging time, this effect is of no consequence with random data signals, but it is a source of error when a single word is repeated many times.

Further improvement in the resonator part of the system is readily possible. Operating with $n = 1$ will reduce the importance of nonresonant transmission, and forks now under development will reduce its level. Since the drive-frequency dependence of the fork is less at low drive levels than at high, grinding the forks to correct frequency with small drive will reduce the dependence of output phase on the number of transitions in the data signal. Still more may be done, but as one seeks still better performance, the cost rises rapidly.

Synchronization Recovery System

A synchronization recovery system has been designed which takes advantage of the good stability and long memory of the tuning fork. The system makes a good estimate of phase because the fork integrates over a large number of transitions. The system is started quickly by initially overdriving the fork. The initial estimate of phase is made on the basis of a few transitions but tends to be accurate because of the constraints on the signal. During the start period the signal is required to be rhythmic mark-space and the fork drive is inhibited until the mark to space ratio nears unity.

The system which has been built uses a 1,600 cps (cycles per second) tuning fork. It can provide timing for either an 800 or 1,600 bit per second signal. For 800 bits per second the fork operates on the second harmonic of its input, the fork output frequency is divided by two. The division is controlled so that only one of the two possible output phases is allowed.

SYSTEM BLOCK DIAGRAM

The block diagram is shown in Fig. 1. The arrangement for 800-bit-per-second operation is shown since this is the more complex case. The signal input to the synch recovery circuit is a binary wave, reconstructed in amplitude but jittered in time. This wave is differentiated and full-wave rectified to produce positive pulses marking the transitions of the input wave. These pulses are applied to the signal circut and the control circuit.

SIGNAL CIRCUIT

The pulses marking the transitions are applied to a gate which is enabled when the control circuit indicates that the synchronizer input has acceptably low distortion. The output of this gate drives a single-shot multivibrator which generates pulses whose length is a half period of the oscillation of the fork. These pulses are passed through an attenuator to the fork driver which applies them to the tuning fork itself. The attenuator is initially set for low loss to provide high drive for the fork during the start-up period. When the control circuit supplies a signal indicating that adequate time has been provided for the build up of the fork, the attenuator is switched to a much higher loss. This loss reduces the drive to that which is necessary to maintain the amplitude of fork oscillation at the desired level.

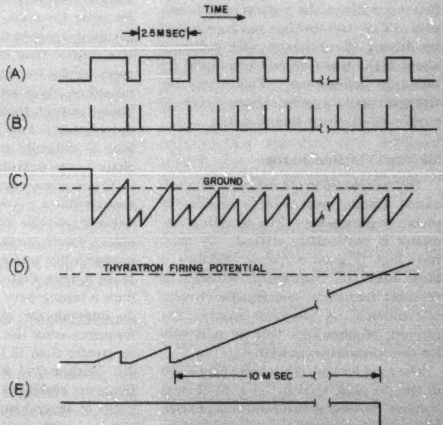

Fig. 2. Waveform diagram illustrating control of thyratron 1

E—Fork out
F—Limiter out
G—Delay multivibrator in
H—Delay multivibrator out
I—Flip-flop in
J—Flip-flop output

The output voltage of the fork is passed through a limiting amplifier which converts it to a rectangular wave. The rectangular wave is differentiated, generating pulses to drive a delay multivibrator which in turn drives the output flip-flop. The delay multivibrator corrects for accumulated phase shifts in the recovery circuit and is made adjustable to permit matching the transitions in the output with the transitions in an unjittered signal. The output flip-flop counts down by two from the frequency of the fork and provides a square-wave output in which both transitions are accurately timed. The two outputs of the flip-flop are applied to isolating amplifiers which in turn drive the connected loads.

CONTROL CIRCUIT

Pulses marking the transitions are fed into the time comparator circuit. This circuit is an integrator which responds to the pulses as shown in Fig. 2(C). Whenever the time comparator output exceeds ground, it causes the resetting of the delay, see Fig. 2(D). When the mark and space periods approach equality, the time comparator output no longer exceeds ground, and the delay is no longer reset. The delay is another intergrator which charges about eight pulse periods before reaching a thyratron firing voltage. When the thyratron fires the circuit knows that the mark and space periods have become about equal and have stayed that way for several periods. It is assumed, therefore, that severe distortion is ended. When the first thyratron fires it enables gate 1 and starts a delay. After about 20 milliseconds the second thyratron fires, reducing the drive on the fork and enabling gate 2 to apply pulses to the output flip-flop.

The firing of the second thyatron must be synchronized with the input signal to insure that no ambiguity occurs in the output. Wave shapes of Fig. 3 indicate how that is accomplished. The pulse generator of the signal circuit generates 312.5-microsecond pulses; see Fig. 3(B). This wave is differentiated so that the positive pulses correspond to the delayed transitions. The differentiated pulses are fed to the thyratron grid where they are superimposed on the charging curve of the delay integrator; see Fig. 3(C). The second thyratron fires after a delay of about 20 milliseconds and at the occurrence of a positive pulse. Note that the voltage change between pulses is less than the amplitude of a positive pulse, assuring that the thyratron will actually fire on a pulse. The first pulse out of the delay multivibrator after the thyratron fires is gated to the output flip-flop; see Fig. 3(I). This mode of operation allows 312.5 microseconds of jitter on the input wave without incorrect starting. With the relative phases and voltages shown in Fig. 3, the output flip-flop is constrained to start with a negative going transition at the bit center.

Results

The timing of the output of the synchronization recovery system is slightly affected by the frequency drift of the transmitting oscillator and by the input code. The output transitions vary about 6 microseconds relative to the input transitions for a frequency drift of 7 ppm. The drift will be less than 7 ppm if the transmitter is tuned periodically. The input code to the system is expected to be nearly random, which implies that on the average, half the possible transitions will be present. If the timing is accurate when 50% of the transitions are present, an error of 6 microseconds will occur when a code with only 40% of the transitions present is applied continuously. However, it is highly unlikely that only 40% of the possible transitions will occur for a time comparable to the memory of the fork if the code is nearly random. Therefore, the error due to the variation in the code is expected to be very small.

Tests were run on the effect of jitter. Fig. 4 shows the relation between the jitter of the recovered timing wave and the jitter of the input wave. The figure shows that the jitter has less effect at the 1,600 bit rate. When the input jitter exceeds 25%, the output flip-flop will sporadically miss a count. This will cause the 800-bit-per-second output to jump 180 degrees. This effect does not occur

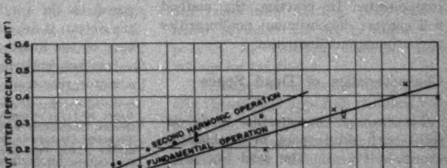

Fig. 4. Jitter characteristic of synchronization recovery circuit. For this experiment input and output jitter distributions were approximately Gaussian

at 1,600 bits since no frequency division is used at this bit rate.

Conclusions

The synchronization recovery circuit which has been described provides an accurate timing wave in the presence of transmitting oscillator drift, variation of codes, and jitter. If the transmitting oscillator is adjusted periodically and the data are nearly random, timing errors due to oscillator drift and variation of codes will be small. The major timing error will be due to jitter. Operation at fundamental has greater tolerance to jitter. Furthermore, fundamental operation is simpler since the output phase is determined without ambiguity.

The synchronization recovery system has been used in tests of data transmission over telephone circuits. Performance was generally excellent and was consistent with laboratory results.

Linearization of Dead Space

SHELDON JONES
ASSOCIATE MEMBER AIEE

Synopsis: The characteristics of dead space are reviewed, and a method of converting the discontinuous nonlinearities of dead space to a linear characteristic or, at least to a continuous nonlinearity, is outlined.

DESIGNERS of most physical systems have a wealth of information available for the synthesis of linear systems. Of course, the reaction of a true system to small perturbations will not be precisely as predicted because of the linear approximation of the system differential equations, i.e., assuming constant coefficients from one signal level of operation to another. Fortunately, the linearization of continuous nonlinearities, in general, does not create serious deviations from the stability prediction of linear analysis.

Discontinuous nonlinearities such as static friction, hysteresis, and saturation exist in most physical systems. Extensive theories have been developed for the analysis of this type of nonlinearity. The most common of these theories are those of the phase plane and the describing function. Unfortunately, these theories do not contribute substantially to the synthesis of physical systems of any complexity.

A method is outlined for linearization of dead space or backlash with ideal components. In practice, the method will convert discontinuous nonlinearities to continuous nonlinearities.

Characteristics of Dead Space

The transfer characteristic of an element with dead space or backlash is shown in Fig. 1. The solid line is an idealized plot of output versus input for an element with this characteristic. The dashed portion of the transfer characteristic represents more nearly the output-input relationship with actual components. The output of the idealized device to a specific sinusoidal input is plotted in Fig. 2. A Fourier analysis[1] of the output waveform yields the following equations:

$$y(t)=C_1 \sin \omega t+\sum_{n=3,5\ldots}^{\infty} C_n \sin n\omega t \tag{1}$$

where

$$C_1=\frac{EK}{\pi}(\pi-2B+\sin 2B)-\frac{4Kb \cos B}{\pi} \tag{1A}$$

$$C_n=\frac{4K}{\pi}\left[\frac{E}{1-n^2}(\sin nB \cos B - \eta \sin B \cos nB)-\frac{b}{n}\cos nB\right] \tag{1B}$$

$$B=\sin^{-1}\frac{b}{E} \tag{1C}$$

An input to a system of this type must exceed a certain magnitude before an output is obtained. When the signal amplitude is twice the dead space, the third harmonic amplitude is approximately 29% of the fundamental frequency amplitude. When the signal amplitude is 1.156 times the dead space, the third harmonic is 67% of the fundamental. For large values of threshold the harmonic content of the output waveform becomes appreciable when compared to the fundamental. Of course, the output is dependent upon the amplitude of the input signal.

One frequently used design criterion for a motor gear train driven position servo is to take the feedback from the motor instead of the load, if possible. One of the reasons for this is that backlash in a gear train creates stability problems, and sustained oscillation of a magnitude larger than the backlash may occur if the feedback is taken after the gear train.

In some systems is is imperative to control the position accuracy of the load to a high degree; an example of this is the control of an airplane's elevator to maintain constant altitude in a turn (often referred to as a co-ordinated turn). Any inaccuracy in the elevator position of the order of a gear train backlash can cause serious deviations in altitude. In a system of this type motor position feedback might not give the desired accuracy.

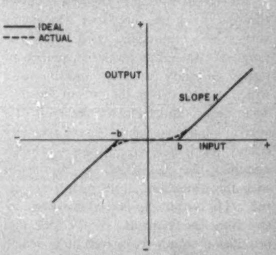

Fig. 1. Output-input relationship for a device with dead space or backlash

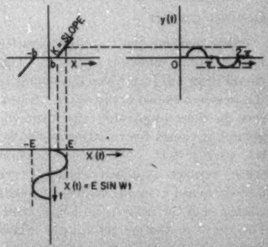

Fig. 2. Effect of dead space on output waveshape

Paper 58-1174, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted February 27, 1958; made available for printing August 4, 1958.

SHELDON JONES is with the Hughes Aircraft Company, Culver City, Calif.

Of course, in certain types of systems a sustained oscillation of small magnitude may not be objectionable.

Linearization of Deadspace

An inspection of Fig. 2 shows that, over a region corresponding to an input signal of small amplitude, no output is obtained; for inputs of larger magnitude an output is obtained. This suggests that if the signal were superimposed on a square wave carrier proportional to the dead space, the effect of the dead space could be minimized. Another method of accomplishing the same thing is to provide infinite gain in the region of zero signal and finite gain for other amplitudes. The characteristics of such a device are shown in Fig. 3(A).

A Fourier analysis of the output for a sinusoidal input of the form $E \sin \omega t$ is

$$f(t) = EK \sin \omega t + \sum_{n=1,3,5,7\ldots}^{\infty} \frac{4a}{n\pi} \sin n\omega t \tag{2}$$

An inspection of Fig. 3 reveals that the output consists of the input sine wave plus a square wave.

Fig. 4 depicts a system where a nonlinearity of the form shown in Fig. 3 is connected in tandem to the nonlinearity form shown in Fig. 1.

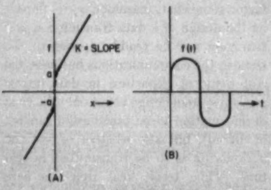

Fig. 3. Input-output characteristic of nonlinear amplifier

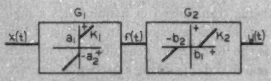

Fig. 4. Block diagram of dead space and nonlinear driver

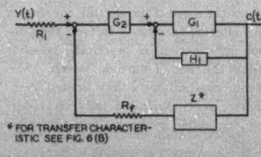

Fig. 5. Functional diagram of high-gain nonlinear amplifier

The input-output relations for block G_1 are

$$f(t) = K_1 x(t) + a_1;\ x(t) > 0 \tag{3}$$

and

$$f(t) = K_1 x(t) - a_2;\ x(t) < 0 \tag{4}$$

The equations for block G_2 are

$$y(t) = K_2[f(t) - b_1];\ f(t) \geq b_1 \tag{5}$$

and

$$y(t) = K_2[f(t) + b_2];\ f(t) \leq b_2 \tag{6}$$

Substitution of equation 3 in equation 5 yields

$$y(t) = K_2[K_1 x(t) + a_1 - b_1];\ x(t) > 0 \tag{7}$$

and for $a_1 = b_1$

$$y(t) = K_2 K_1 x(t);\ x(t) > 0 \tag{8}$$

Similarly, substitution of equation 6 gives

$$y(t) = K_2[K_1 x(t) - a_2 + b_2] \tag{9}$$

and, for $a_2 = b_2$,

$$y(t) = K_2 K_1 x(t);\ x(t) > 0 \tag{10}$$

An inspection of equations 3 and 4 shows that for $t = 0$, $f(t)$ will be $+a$ or $-a$. Therefore, it is concluded that

$$y(t) = K_2 K_1 x(t) \tag{11}$$

for all inputs to the system.

Construction of Nonlinear Amplifier

The input-output relationship exhibited in Fig. 3(A) can be achieved by building an amplifier with infinite open-loop gain and operating the amplifier open-loop closed-loop as a function of output voltage. That is, feedback could be applied to the amplifier at a certain magnitude of output voltage. Fig. 5 is a block diagram of such a system. The inner loop transfer function G_1H_1 can be made an unstable loop. This would approach infinite gain with the outer loop open. The outer loop can be stabilized for values of output voltage greater than the dead space exhibited by the feedback element Z. Ideally, the feedback Z would offer infinite impedance up to a certain level and zero impedance above this level of output. In addition, it might be desirable to make the insensitive zone of Z asymmetrical, in the event of asymmetrical dead zone in the load.

A device exhibiting the characteristic of the feedback element Z is shown in Fig. 6(A). The device consists of two Zener diodes connected "back to back," i.e., either the anodes or cathodes tied together.

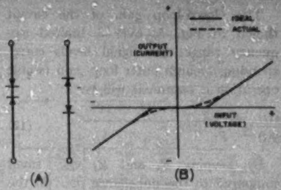

Fig. 6. Nonlinear feedback element

A—Back-to-back connection for Zener diodes
B—Output-input relation of A

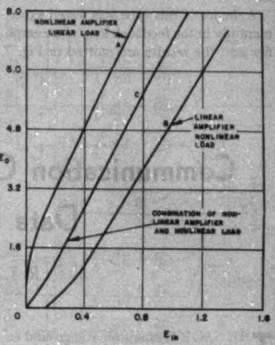

Fig. 7. Experimental data

A Zener diode exhibits the property that very little current flows when reverse voltage is applied to the diode until the breakdown or Zener voltage is reached. For voltages applied in excess of the Zener voltage the diode is equivalent to a resistor and a battery in series. When two diodes are tied together, as shown in Fig. 6(A), the input-output relationship is as shown in (B), where current is considered the output and voltage is considered the input. The input-output relationship of Fig. 6(B) can be made asymmetrical as a function of polarity by choosing different Zener voltage for the diodes.

The Zener diode combination, if properly chosen, will approach the ideal characteristic for the feedback element Z of Fig. 6(B) (see dashed and solid line). Actually, this "nonideal" characteristic may be desirable since in practice dead space exhibits the same characteristic (see dashed line of Fig. 1).

The closed-loop gain of the circuit shown in Fig. 5, over a limited frequency range, for signal levels corresponding to high outer loop gain (stable operation is assumed) will be

$$\frac{c(t)}{y(t)} = \frac{R_f+Z}{R_1} \tag{12}$$

By keeping R_1 and R_f very small compared to the impedance of Z in the "conducting region," the amplifier will appear to be operating without feedback; i.e., the feedback resistance will be infinite. In the conducting region the amplifier gain will be given by equation 12.

A device of this type was tested experimentally in the feedback loop of an amplifier and the results are plotted in Fig. 7. The amplifier, a low-gain amplifier, was chosen because of availablity.

Fig. 7, curve B, is a plot of output versus input when the amplifier was operated as a linear amplifier driving a nonlinear load. With the Zener diodes in the feedback loop, the input-output relationship of the nonlinear amplifier driving a linear load is shown in curve A, Fig. 7. When the nonlinear amplifier was used to drive a device with dead space, the input output relation of curve C, Fig. 7 was obtained.

Conclusions

In a system with dead space, the use of a nonlinear amplifier such as has been described yields the following advantages:

1. The stability of the system is improved and the possibility of low-level oscillations is minimized.
2. The sensitivity in the low-signal region is increased.
3. It tends to linearize the input-output relationship of the open-loop system.

The conversion of the discontinuous type of nonlinearity to a continuous nonlinearity allows the designer to base stability prediction on linear analyses. In addition, the designer of position feedback systems has more latitude in choosing the output feedback point.

Communication Channels for SAGE Data Systems

R. T. JAMES
NONMEMBER AIEE

THE SAGE (semiautomatic ground environment) System is a system of air surveillance and control designed to aid in the air defense of the continental United States. In this system of air surveillance, flight information is transmitted from radars and other sources to a central point where it is processed and evaluated to form a comprehensive picture of the air situation. This picture covers the search area of several radars, thus providing centralized surveillance of a sizable geographic area. The provision of this surveillance capability requires the evaluation of a large amount of information. In addition, to be of any practical use, the surveillance picture must not lag the actual air situation by any very appreciable interval of time. To accomplish this, the flight information must be gathered and evaluated very rapidly. This has been accomplished by minimizing the use of human beings in the surveillance system and leaning heavily on automatic methods. The various automatic data units in the SAGE System are, however, geographically scattered and must be interconnected so that they can process and exchange the flight information. This interconnection is made by special communication systems called data transmission systems which will be described herein.

Basic Considerations

There are several basic factors that have influenced the broad concept and ultimate design of these SAGE data transmission systems.[1] First and foremost among them is the fact that because of the very nature of the air surveillance problem, the SAGE System always works to some degree in real time. A second factor, so closely related to this as to be almost inseparable from it, is the accuracy with which the whole system must handle the continuous flow of information on which the air surveillance picture is based. A third factor of importance is the sheer size of SAGE. By any yardstick, it is a large project; geographically, for example, it covers the continental United States. Finally, and this is mainly of interest from the communication standpoint, the various data units to be interconnected are usually located in remote and sparsely settled areas.

Real Time

It is appropriate at this point to amplify the significance of the foregoing real-time factor somewhat, inasmuch as its impact on the design of a data transmission system may not be readily apparent. To those in the communications business, the real point of departure in data transmission system design is not only the type of information to be transmitted (analog or digital), but also whether or not the information is to be transmitted in real time. (The term "real time" is here loosely used.)

Real time is applied rather generally to those data transmission systems and data applications where the information being transmitted or handled has a high rate of obsolescence. An example of this is the information generated by a modern search radar tracking a particular aircraft. The position of the aircraft is known each time it is illuminated by the radar beam. This position report is obviously valid for only a short interval of time, and the higher the speed of the aircraft, the shorter this interval becomes. In fact, the position information is practically obsolete within the time of one radar sweep. Also the information has a very limited availability; it is generated only once during the radar sweep for any particular aircraft.

This is a fair sample of what is classed here as a real-time application. Most

military data systems either for weapons control or surveillance are in this class; they vary only in the rate at which the information they use becomes obsolete and in the effects of obsolete or erroneous information on the operation of the overall system. It will be recognized that the real-time term as used here has various possible gradations, depending on the requirements of the particular system under consideration.

The main effect of this real-time factor on the design of a data transmission system is in the fundamental approach to the error problem. The data information is only available for transmission once, there is time enough to send it only once, and it can be received only once. In such a system, techniques of error correction tend to be of limited utility; techniques of error detection and eventual discard of erroneous information seem more practical and are of correspondingly greater importance. The incidence of errors throughout the system must, therefore, be kept small. In the interconnecting data systems this leads to the most rugged transmission systems possible consistent with bandwidth considerations, and to the control of noise in the transmission paths to the fullest extent practicable.

Error Rate

At present, excluding other connecting weapons systems, there are three main types of data systems used in the SAGE System. Grouped according to use, these are ground-to-ground, ground-to-air, and radar data systems. All of these systems do not work in real time to the same degree; neither do they have the same accuracy or error rate requirements. There may be actually two error rates to be considered for any particular system. The first is more or less conventional in that it is intended to be a short-term or minute-to-minute requirement: no more than one received error per 100,000 bits of information transmitted. The second error rate requirement is a longer term consideration and takes the form of a reliability requirement: no system outage or gross system malfunction to exceed 30 seconds.

The first of these requirements has been translated in terms of allowable circuit noise and has greatly influenced the engineering SAGE data systems. This was an early evalution of the short-term accuracy requirements; it is now generally appreciated that a blanket error rate of 1/100,000 represents a somewhat oversimplified view but it is still reflected in the engineering of all data systems. The second requirement is not applied to all data systems but only to those that are very important in the operation of the SAGE System.

Data Circuit Arrangements

Fig. 1 shows the two general data circuit arrangements used. (The data cir-

cuit terminal apparatus in each case is known as the "Western Electric *A1* digital data-signaling system.")[2] Circuit arrangement in Fig. 1(A) is used when the 30-second outage requirement is not applicable and normal circuit restoration times are satisfactory. Only one data path is provided; this arrangement is called a "nondual (or single) data circuit." In cases where the 30-second outage limit is applicable, the circuit arrangement shown in Fig. 1(B) is used. This is a dual (or duplex) data circuit. Two separate data transmission paths are provided between the data-processing units. At the transmitting end, both paths are fed simultaneously through a simple resistive network. At the receiving end of the circuit, trouble-sensing circuits (TR DET) capable of detecting major circuit troubles control a line switching arrangement that switches the data-processing apparatus to the alternate line whenever the working line goes in trouble.

A signaling system is also associated with this line switch circuitry that indicates the status of both transmission paths. Line transfers, although they result in a considerable number of errors, are accomplished in well under the 30-second limit. Substantially the same trouble-sensing apparatus is supplied with the nondual data circuits, excepting, of course, the line switch. In this application, status indications only are available. The actual physical routes used by both types of SAGE data circuits are chosen in accordance with certain military considerations. In the case of dual data circuits, the *A* and *B* routes are widely separate over all but a small part of the total distance between the data-processing units.

Data Circuit Characteristics

At the terminal points of the data circuits, information is exchanged with the data-processing units in the form shown in Fig. 2(A), the input, and (B) the output. Three separate informational components exist at these points: start, data, and timing. The start component indicates the beginning of a message, the data component contains the message information, and the timing component provides means of accurately synchronizing the data-processing units connected to the circuit.

Data circuits utilized in SAGE are designed to transmit information at two speeds, either 1,300 or 1,600 bits per second. The timing component is a continuous sine wave of either 1,300 or 1,600 cps (cycles per second) depending on the bit rate. The message information is carried by a series of marks and spaces on the data path. Marks are indicated by single cycles of either 1,300 or 1,600 cps frequency (dipulses), in the correct time slot. Spaces are no signal. The start of a message is indicated by a single mark on the start path, again a single cycle of either of the aforementioned frequencies depending on the bit rate. Fig. 2(A) and 2(B) illustrates a mark-space sequence on either of these last two paths.

At the sending end of the data circuit, the amplitude of the dipulses and the continuous timing wave is nominally 2.2 volts, peak to peak. At the receiving end of the circuit, these components can be delivered at substantially the same level if the data-processing apparatus and the receiving data terminal are close together. Otherwise they are adjusted to 0.5-volt, peak to peak, thus providing an allowance for path loss between the data terminals and the processing units. The impedances terminating the dipulse paths are 600 ohms, resistive.

Fairly stringent tolerances are placed on these signals. The timing component has both the conventional long-term stability requirement (expressed as a time between zero crossings), and also a short-term or cycle-to-cycle limit called "jitter." The data and start components are tied quite tightly to the timing through most of the bit interval by the instantaneous phase variation limit of ±1%. The data-processing units obtain information from these dipulses by interrogating only a few microseconds of the bit interval, usually at either peak of the dipulse. The accurate timing component plus the instantaneous phase tolerance insures the correct time position of this interrogation interval. With this technique, the wave-shape at the beginning and end of the bit interval is of minor importance, so the tolerances have been relaxed at these points to allow reasonable transients. The permitted level variations come out to be about ±1 db (decibel) at the data circuit input and ±1.5 db at its output. The allowable peak signal, peak noise ratios at these same two points, are 30 and 20 db respectively.

It may be noted that the differences between the dipulse signals at the input of the data circuit and those at its output are minor; the transmission is substantially distortionless. The dipulses, however, are transmitted as such over only a small part of the total length of the data circuit, at most a few miles. In the transmitting data terminal, the dipulse information is modulated on a suitable carrier (2,000 cps). This modulated signal is transmitted over specially treated voice bandwidth facilities to the receiving data terminal, where the information is extracted and regenerated in the original dipulse form.

This regeneration technique is also applied to the timing component which is regenerated by a local oscillator in the receiving data terminal that is periodically synchronized on each start pulse. The method of deriving timing limits the time between start pulses inasmuch as the local oscillator stability must be such that it can free-run for this period accurately enough to meet the requirement of Fig. 2. A system of this kind is therefore limited in the message lengths that it can handle. The 1,300-bit data system is designed to handle message lengths up to about 300 bits. The 1,600-bit system is designed primarily for message lengths in the neighborhood of 60 bits.

Not all of these bits can be used to carry information. The two bits preceding the start pulse (end of one message) and the two bits following it (beginning of the next message), must be identical. In the SAGE System, for example, the start pulses are always preceded and followed by two spacing bits. It may be noted also that this timing scheme is not capable of reproducing wide timing variations. About the maximum variation it can follow is ±0.01%, or ±0.13 cycle in the 1,300-bit system and ±0.16 cycle in the 1,600-bit system.

The SAGE data circuits are designed for continuous operation, i.e., meaningful messages or blank message frames are on the line at all times. The circuits are not designed for, nor are they capable of, start-stop operation. Neither are they designed to take rapidly and widely varying message lengths. In the SAGE System the message lengths vary from about 60 to 300 bits, depending on the circuit use, but the message length on any particular circuit remains fixed. It seems probable, however, that a given circuit could handle a moderate variation in message length although no performance tests have been made under these conditions. It may be noted here also that the same data terminal apparatus is not used for both the bit rates that have been discussed here. Different versions of the *A1* digital data signaling system are used for each speed.

Data Circuit Line Facilities

It is mentioned earlier that the sending and receiving data gear at the circuit terminals are interconnected by specially treated voice bandwidth facilities. It is now appropriate to describe briefly what this special treatment amounts to and how it affects the engineering of these line facilities.

Because of the extent of the SAGE System and the number of data circuits that it requires, it has seemed imperative from the beginning to avoid special treatment of the line facilities as far as possible. It has seemed equally imperative that the existing national network be used to the fullest extent practicable. This network comprises all types of line facilities, both voice frequency and carrier. Significant economic penalties would accrue if any very large slice of this network could not be used for SAGE data transmission. A given route, for example, may be developed for a certain type of carrier, and if this carrier cannot be used, another route must be found. To provide a limited network, this may well be possible and a considerable amount of this selection of facilities and routes is constantly done in the furnishing of special services. The larger the desired network, however, the less practical this process becomes and it seems entirely impractical for a network the size of that required for SAGE. These two factors, use of the national network and a minimum of special facility treatment have, in fact, been basic in the SAGE concept.

As used here, the term "special treatment" includes measures over and above those normally involved in the provision of a circuit for standard voice message purposes. For the data circuits, this special treatment comes down to two main areas of activity. The first of these is the provision of delay equalization.

A standard message circuit will generally have significant differences in transmission time between various parts of the frequency spectrum. This is of little consequence for voice use but of considerable consequence for data, telephotography, and allied applications where the rate of information flow is much higher. This difference in transmission time, or delay, varies with the type of facility in question, and in some types of facilities it also varies with the circuit length. This distortion results in different frequency components of the signal arriving at the receiving end of the circuit at different times, and unless it is corrected, a degradation of the signal results.

To alleviate the effects of this distortion, it is customary to use only the part of the available circuit bandwidth that can be readily equalized. The least distortion will be found in the middle range of the circuit bandwidth; it is much greater in the upper and lower circuit cutoff regions. In the SAGE data circuits, these cutoff regions are not used at all, the line signal energy of the *A1* data system being confined to the region from 1,000 to 2,600 cps. (The signal pass band must be limited and shaped, in any case, for other reasons.) The delay distortion in this region is held to within ±250 microseconds; in most cases, delay equalization must be added to keep within this limit. The limit itself was set on the basis of telephotograph experience and theoretical consideration of the SAGE requirements.

Each type of line facility has an individual and distinctive delay distortion characteristic. It is possible, therefore, to predict the distortion characteristic for any data circuit providing its make-up (the types and lengths of line facilities comprising it), is known. With the distortion characteristic known, it is entirely practicable to apply the appropriate equalization to reduce it. Circuits can be equalized in this manner to a reasonable degree of precision if the circuit make-up information is accurate and if no impedance irregularities exist. This is the general method used to equalize the data circuits for SAGE; it is a prescription process rather than a measurement process. The technique also includes procedures designed to expose any impedance irregularities that may exist; this has been found to be essential. Not all circuits can be equalized with this method, some makeups are so complex that an actual measurement must be made. Fortunately, this holds for only a small minority of the data circuits. In conclusion, it may be noted that the delay distortion characteristics of the circuits are fairly stable and, for the circuit lengths involved in SAGE, relatively little seasonal change may be expected.

The second major area of effort has been in the control of circuit noise. As pointed out earlier, SAGE data circuits work to some degree in real time and the emphasis has necessarily been on cutting down the incidence of errors rather than their correction. This, in the end, becomes a problem of circuit noise.

It may be noted at the outset that the national network was, and is, still being built primarily for the transmission of information via the spoken word. Any added use of it, such as data transmission, involves an adaptation process to reconcile conflicting technical requirements or to meet new ones. Although this may be a troublesome job, the economic advantages attendent on it make it well worth while.

The noise situation is a good example of this. The frequency response of the human ear is not flat but is peaked in the middle range of audible frequencies, around 1,000 cps. Above and below this, its response falls off, particularly so in the region below about 500 cps and above about 2,500 cps. This has been considered in the engineering and construction of the national network and its basic noise characteristics reflect this kind of a weighting. The net result is that any other user of the network that does not have this built-in-weighting is likely to encounter comparatively high noise, particularly at the low end of the spectrum. Another human characteristic of interest in this regard is the response time or "time constant" of the ear. It has been found that noise meters with a time constant of 200 milliseconds (plus the appropriate weighting) give the most accurate gage of the effect of circuit noise on normal voice transmission. Noise bursts of shorter duration than 200 milliseconds have correspondingly less effect and their effect continues to decrease as their duration time shortens. This, also, has been reflected in the engineering of the national network so that, in addition to their weighting, the circuit noise characteristic may show sporadic short-noise peaks that may range anywhere from 10 to 50 db above the average or steady-noise level.

The rate of occurrence of these noise bursts, called impulse type noise, as well as their peak factor, will vary with the type of facility. Actually, it depends on the noise exposure; some types of facilities, particularly some types of carriers, work under more severe noise exposures than others because of their area of application in the telephone plant. The sources of this impulse noise are many and varied, the two main causes being atmospheric static disturbances and circuit switching operations.

So far as the SAGE data systems are concerned, the effect of both the network noise weighting and the average circuit noise level is not controlling. As noted, the signal spectrum is carefully shaped and limited, so the *A1* system normally operates in the part of the circuit bandwidth where the noise is most carefully controlled. Furthermore, the weighted average noise level on any normal circuit is not likely to be such that it will impair the operation of the data system. The level of this noise is held to that acceptable to human beings and they are much less tolerant than the SAGE data systems in this respect.

The opposite is true of impulse noise. The SAGE data systems are much less tolerant of this type of noise than human beings. The information carried by these systems is in digital form with the bit intervals less than one millisecond in length. The level of impulse noise of this or shorter duration intervals accordingly constitutes our main concern in the whole noise area. It has recently been determined that errors in transmission generally occur only when the magnitude of individual noise peaks exceeds about −15 dbm (decibels referred to one milliwatt) at the zero dbm transmission level point. Plans now under preparation make necessary modifications in various techniques of circuit design and noise measurement to reflect this criterion. The design techniques vary with the facility involved; most of the work in this area concerns the shorter haul carrier systems because they operate at lower line levels than have heretofore been employed.

The accomplishments in both the noise and delay problem areas have borne fruit in making possible the widespread use of the company's national network for SAGE data circuits. All the standard Bell System type of facilities except circuits with heavier loading than *H* or *B88*, and one older type of carrier, are being used for this purpose at present. These exceptions do not represent a significant part of the network.

One further point may be noted with respect to facilities. The choice of dipulse signals as the input and output signals of the data circuits eases considerably the problem of connecting the data circuits and the data-processing apparatus. In most cases, separation of the data circuit terminals and the data-processing apparatus has been found to be desirable and necessary. These dipulse signals permit this; they can be transmitted quite readily for several miles if necessary.

Performance

This summary of the main features of the data circuits provided for the SAGE System would not be complete without a few words as to their performance. Only a limited number of circuits are presently in service but these results are also being supplemented by a rather extensive field testing program designed to check error performance. On the basis of this experience, it seems that the 1/100,000 blanket error rate, roughly one error per minute, is generally met if the errors are averaged over a fairly long period, at least several hours. The normal circuit performance is not a fairly constant incidence of errors from minute to minute but many minutes of absolutely error free transmission followed by a burst of errors, or errors equivalent to a burst, then error-free transmission again.

Conclusions

Transmitting information in real time seems likely to be a problem for some time to come. The SAGE System is only one example of it; many more applications presently exist or are in the planning stage. This paper represents one approach to the problem; other approaches are possible and are, in fact, being tried. It seems probable that the experience gained in this and other data systems will ultimately indicate the best technical and economic solution of the real-time data problem.

The Ferroresonant Circuit

GEORGE E. KELLY, JR.
ASSOCIATE MEMBER AIEE

A CIRCUIT which consists of capacitance in series with an iron-core reactor, with or without other circuit elements, may be a ferroresonant circuit. Ferroresonance, as the term indicates, is resonance associated with circuits in which at least one of the circuit elements contains iron and which is a nonlinear inductive element. Resonance in any series circuit occurs where the inductive and capacitive reactances are equal. In a given series circuit of linear resistance, inductance, and capacitance, there is only one frequency of applied sinusoidal voltage at which resonance will occur; but at this frequency, resonance occurs at all values of applied sinusoidal voltage.

A circuit with linear resistance and capacitance in series with an iron-core reactor, regardless of the frequency of the applied sinusoidal voltage, will be a ferroresonant circuit if, at some value of applied voltage, the inductive and capacitive reactances are equal. The resistance and reactance of the iron-core reactor vary with the degree of saturation in the iron, which depends upon the voltage across the reactor. At negligible saturation, the inductive reactance is high but it decreases as saturation increases. When the capacitive reactance is lower than the inductive the resulting current lags the applied voltage, but if it is higher the current will lead the applied voltage. Harmonics will be present because of the nonlinear inductance but, as will be explained later, their presence does not greatly affect the performance of a ferroresonant circuit except in the region of high saturation.

Fig. 1(A) shows sustained rms current of substantially fundamental frequency plotted versus applied sinusoidal voltage in a ferroresonant circuit. At point y on the ys curve, corresponding to voltage B, the voltage and current are substantially in phase. This is the point of ferroresonance. For other points on the ys curve, the current leads the applied voltage. For values of applied voltage between B and C, there are two possible values of substantially fundamental frequency current, either of which may occur depending upon the residual magnetism in the reactor and the charge on the capacitor at the instant the voltage is applied.

Assume that a value of voltage less than voltage B of Fig. 1(A) is applied to a ferroresonant circuit, and subsequently the applied voltage is increased; a curve similar to $0x$ is traced. At point x, I suddenly jumps to curve ys with the same value of applied voltage corresponding to I at point x on the $0x$ curve. If the circuit is kept closed and the applied voltage varied, curve ys is traced. Under the preceding condition, the circuit will operate to return to curve $0x$ if the applied voltage is decreased to point y on the ys curve, corresponding to applied voltage B. The return from curve ys to $0x$ may also be accomplished if the circuit is opened and closed one or more times in the region between applied voltages corresponding to points B and C.

Fig. 1(A) and the foregoing description of the simplest type of the ferroresonant circuit may be obtained from previously published papers,[1–9] where the possibility of subharmonic currents and voltages is also discussed.

Previous Investigation

Several of the many papers just mentioned dealing with the ferroresonant circuit have been delivered before the AIEE.[1–9] As indicated by their titles, they are chiefly concerned with subharmonic voltages and currents which may be present. The usual subharmonic components in a 60-cycle circuit are those of the second and third order, with frequencies of 30 and 20 cycles per second respectively.

The ferroresonant circuit is of interest because of its possible application to relays and control devices,[1,3,4] and because of its application, when extended, to the problem of open conductors in 3-phase circuits. In this latter application, interest is centered on the magnitude of the resultant voltage across the nonlinear reactance, and its phase relative to that of the impressed voltage.

McCrumm,[9] in reporting the results on his extensive tests on ferroresonant circuits, although chiefly concerned with subharmonics, gives a clear picture of what may be expected in a ferroresonant circuit. He gives a graph of impressed sinusoidal voltage E versus rms current I in the circuit. A similar graph is shown in Fig. 1(A).

As the impressed sinusoidal voltage is slowly increased from zero to its maximum value, the response of the circuit (its rms current and rms voltage across the reactor) differ in character for different magnitudes of impressed sinusoidal voltage. Referring to Fig. 1(A), it may be seen that for any value of E between 0 and B there can be but one

Paper 58-1168, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted January 22, 1957; made available for printing July 30, 1958.

George E. Kelly, Jr. is with the Prairie View Agricultural and Mechanical College, Prairie View, Tex.

The author gratefully acknowledges the helpful suggestions of Profs. Edith Clarke and William C. Duesterhoeft of the University of Texas, in the preparation of this paper.

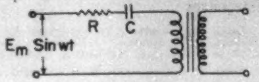

Fig. 2. A ferroresonant circuit

value of *I* (a possible exception will be mentioned later). For any value of *E* above *C*, there is but one possible value of *I*. For values of *E* between 0 and *B*, *I* lags *E*; for values of *E* above *C*, *I* leads *E*. For values of *E* between *B* and *C*, Fig. 1(A) shows two possible values of *I*. In addition to these two values, McCrumm has shown that subharmonics of both the second and third order may occur for values of *E* between *B* and *C*, and also for values of *E* below *B*.

In a paper published prior to McCrumm's, Odessey and Weber[5] give methods for determining critical values, or points of discontinuity. The points *x* and *y* on the curve 0*x* and *yz* of Fig. 1(A) are points of discontinuity. They also show a graph of curves similar to the curve of Fig. 1(B), and point out that the sections of the curves where the rate of change of current with applied voltage is negative, although satisfying voltage-current equations, does not give stable operating points. In Fig. 1(B), points on the curve between *x* and *y* are unstable points. This agrees with the graph of Fig. 1(A) where no connection is shown between points *x* and *y*.

In some of the published papers on the ferroresonant circuit, extensive test data are given, without accompanying calculations to check test data; in others, equations are developed based on theory without accompanying tests. So far as the author has been able to determine, no publication gives both test results and calculations to check test results for a specified ferroresonant circuit. Because of this lack, the present study was undertaken.

Purpose of This Study

This study of the ferroresonant circuit was undertaken for the following purposes:

1. To determine whether the rms currents in the circuit and the rms voltages across the nonlinear reactor, under various values of applied sinusoidal voltage, can be satisfactorily predicted from calculations in which rms currents and voltages are treated as if they were of fundamental frequency only.
2. To predict the probability of the occurrence of each of two possible voltages across the reactor in a region where either is possible.
3. To observe subharmonic voltages across the nonlinear reactor, if present, and to record the conditions under which they occur.
4. To illustrate the application of the ferroresonant circuit to the problem of open conductors in 3-phase circuits.

The paper is divided for convenience into four parts, each dealing with one of the stated purposes for which this study of the ferroresonant circuit was made.

As the same type of circuit and the same iron-core reactor were used throughout, they will be described before stating the methods used in calculations and in making tests.

The circuit studied consisted of resistance and capacitance in series with an iron-core reactor, the iron-core reactor being the 120-volt winding of a 2-kva, 120- to 240-volt, single-phase transformer with the 240-volt winding on open circuit. A 60-cycle sinusoidal voltage of variable magnitude was applied to this circuit, in which resistance and capacitance were given several different values; see Fig. 2.

The excitation characteristics of the reactor are given in Fig. 3. In Fig. 3(A), rms exciting current is plotted versus rms applied sinusoidal voltage; in Fig. 3(B) and (C) respectively, rms magnetizing and power components of exciting current are plotted versus the applied rms sinusoidal voltage.

Calculations and Test for the Same Ferroresonant Circuit

Two methods of calculation were used, both making use of the excitation characteristics of the reactor. In both methods, all currents and voltages were treated as if they were of fundamental frequency only.

In the first method it was assumed that the total exciting current in the reactor could be considered magnetizing current, with the reactor voltage leading it by 90 degrees. For any assumed reactor voltage, with the corresponding exciting current as reference vector, the vector voltage across the resistance and 60-cycle capacitive reactance in series was added vectorially to the reactor voltage. This gave the applied voltage *E* necessary to produce the assumed reactor voltage. In Fig. 4(A), curve *A* gives the magnitude of the voltage *E*, calculated by the first method.

In the second method, a reactor voltage was assumed and the corresponding magnetizing and power components of the rms exciting current were used to determine the phase of the exciting current relative to the reactor voltage. With reactor voltage as reference vector, the voltage across the resistance and 60-cycle capacitive reactance in series caused by the vector exciting current was added to the reactor voltage to give the applied voltage *E* required to produce the assumed reactor voltage. The phase of the reactor voltage relative to *E* was

also determined. In Fig. 4(A), curve *B* gives the magnitude of the rms current *I* versus the magnitude of the voltage *E*, calculated by the second method.

First Method of Testing

Two methods of testing were employed. The first was used to determine whether test results can be checked, at least approximately, by calculations based on the assumption that rms currents and voltages are of fundamental frequency only. By this method, the procedure was as follows: The switch to the circuit was closed and kept closed, while the applied sinusoidal voltage was varied from zero to a high value. Applied voltages and resultant rms currents were recorded. Then, with the switch to the circuit still closed, the applied voltage was gradually decreased. Applied voltages and rms currents were again recorded.

Results of First Method of Testing

The results of one test by the first method is shown in Fig. 4(A), where rms current *I* is plotted versus applied rms sinusoidal voltage *E*. As *E* was slowly increased up to approximately 45 volts, a smooth curve of *I* versus *E* was obtained; but at $E=45$ volts, *I* suddenly jumped to a higher value. After that, as *E* was further increased, another section of a smooth curve was obtained, as indicated by the small circles. As the voltage *E* was then slowly decreased, *I* retraced its previous path to the point where *E* was approximately 45 volts. It did not jump to a lower value at this point, but continued on the same smooth curve until *E* was approximately 25 volts, and *I* approximately 1.36 amperes. At this point it suddenly jumped to 0.21 ampere at 25 volts. From this point, it retraced its previous path down to zero.

Figs. 4(B) and (C) show the results of additional tests and calculations, with values of resistance and capacitance indicated.

Two Possible Values of Current and Reactor Voltage for One Value of Applied Voltage

As may be seen from Fig. 4(A), if the applied voltage *E* is between 25 and 45 volts, there are two possible values of current. There are also two possible values of voltage across the reactor. This is shown by curve *A* of Fig. 5, where rms voltage across the reactor is plotted versus applied sinusoidal voltage *E*. Figs. 6(A) and 6(B), reading time from left to right, show one period of each of the two possible reactor voltage waves superposed upon one period of the applied sinusoidal voltage of 45 rms volts. The voltage at low current is given in (A); that at high current, in (B). Although the time phase of each reactor voltage wave relative to the applied voltage is correct, no attempt was made to have their amplitudes to the same scale.

In Fig. 7(A), taken at the high current value, the waveforms of the current and reactor voltage are superposed on the applied voltage. In (B), taken at the low current value, the waveforms of the current and reactor voltage are superposed on the applied voltage wave. These curves were also taken at the point of discontinuity, corresponding to an applied voltage of 45 rms volts, and the circuit associated with Fig. 4(A).

Comparison of Calculated and Test Values with Conclusions

For the circuit associated with Fig. 4(A), both methods of calculation, previously described, were used. For applied voltages between 0 and 45 volts,

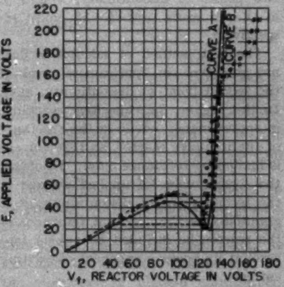

Fig. 5. Voltage characteristics of a ferroresonant circuit

Calculated curves:
A—R=1.475 ohms, C=26.8 μf
B—R=1.475 ohms, C=31.9 μf

Test values:
o—R=1.475 ohms, C=26.8 μf
x—R=1.475 ohms, C=31.9 μf

Note: apparent resistance of reactor included in calculations

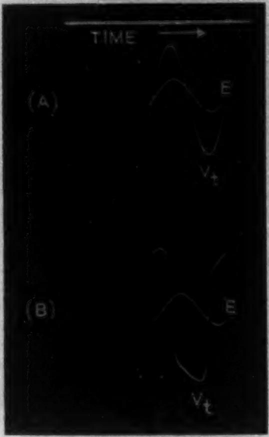

Fig. 6. Oscillograms illustrating phase relationship between applied and reactor voltage before and after jump from low to high current of ferroresonance at point of discontinuity. R=1.475 ohms; C=26.8 µf

the second method of calculation (where the power component of the reactor exciting current is taken into account) gives a better check of test results than the first method (where the exciting current is treated as entirely magnetizing current). It also gives a better check of the two points of discontinuity, x and y, at $E=45$ volts and $E=25$ volts respectively.

The first method of calculation does not give even an approximate check of the second point of discontinuity, at y. In this region, the capacitive reactance is approximately equal to the reactance of the iron-core reactor, so that current is limited by resistance only. To obtain the correct value of applied voltage at the second point of discontinuity, it is essential that the apparent resistance of the reactor be included by taking into account its power component of exciting current.

Because the first method of calculation is easier to apply, it was used in the calculations for Fig. 4(A), the first study made. It is of interest to note that for high values of current it gives a better check than the second method.

In Fig. 4(B) and (C), the second method of calculation only was used, and test results for each case are indicated. In Fig. 4(B), the capacitance used for the curves in Fig. 4(A) was retained, but three different values of resistance were used to show the variation of current and points of discontinuity with resistance. In (C), the resistance for the curves of Fig. 4(A) was retained but three different values of capacitance were used.

The check of test results by calculations may be considered quite good for all circuits considered, with two exceptions. One of these is the circuit associated with Fig. 4(C), having the highest capacitance, where the check is not even approximate for current beyond those at the second point of discontinuity. The second exception is in the high voltage values of Fig. 5.

This second exception is not surprising. At the first point of discontinuity the voltages across the reactor, as shown in Fig. 6(A) and (B), before and after the discontinuity respectively, are approximately sinusoidal and of fundamental frequency. Therefore the method of calculation is reasonable. As the applied voltage is increased, the waveshape does not change appreciably until the applied voltage is far above the rating of the transformer. Then it changes suddenly and, although of the same period, has pronounced harmonics, including even ones. If it is remembered that the applied voltage is from a power source at constant voltage, the application of voltages high above rated transformer voltage is not a practical case in power transmission systems.

A more thorough study should be made of these two exceptions, both of which involve high exciting currents in the reactor, with the idea of developing a method of calculation which will include the effect of harmonics when exciting currents are above a predetermined value.

The phase positions of the reactor voltage waves relative to the applied voltage, shown in Fig. 6(A) and (B) at an applied voltage of 45 volts, agree with calculations. For low values of current, the reactor voltage is almost in phase with the applied voltage. For high values of current, it is almost 180 degrees out of phase with the applied voltage. Thus, there is phase reversal at the points of discontinuity.

A more explicit explanation of linear calculations giving a good check of experimental results is as follows. It may be recalled that a nonlinear reactor generates harmonics, these harmonics being most pronounced in the region of saturation. In view of the preceding statement, it would be expected that linear calculations would give a good check of experimental results, provided the region of high saturation or pronounced harmonics is not entered. Such was the case in this investigation.

A—$E=45$ volts
$V_t=122$ volts
$I_{rms}=1.80$ amperes
B—$E=45$ volts
$V_t=87$ volts
$I_{rms}=0.53$ ampere

Probability of Occurrence

The probability of occurrence of each of the two possible voltages across the reactor when either is possible was tested. The circuit associated with Fig. 4(A) was employed for this test. In this figure it may be seen that for values of applied voltage between 25 and 45 volts there are two possible values of current. There are also two values of voltage across the reactor, as shown in Fig. 5. The question is which is more likely to occur. To answer this question, four types of tests were made.

TEST 1: SWITCH CLOSED AND VOLTAGE VARIED

As the applied voltage was slowly raised from zero to 45 volts, without opening the switch, the lower value of reactor voltage was obtained. At 45 volts there was a jump to higher current and higher voltage across the reactor, and phase reversal. With the switch still closed, and the applied voltage reduced, the higher values of current and

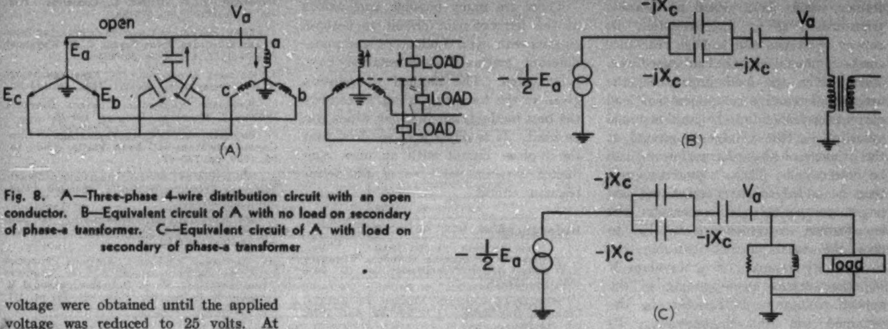

Fig. 8. A—Three-phase 4-wire distribution circuit with an open conductor. B—Equivalent circuit of A with no load on secondary of phase-a transformer. C—Equivalent circuit of A with load on secondary of phase-a transformer

voltage were obtained until the applied voltage was reduced to 25 volts. At this second point of discontinuity there was jump to lower values of current and voltage.

It may be concluded from this first test that, once on a higher or lower voltage path, with the switch closed, there will be no change to the other until points of discontinuity are reached.

TESTS 2 TO 4: VOLTAGES APPLIED TO CIRCUIT BY SUDDEN OPENING AND CLOSING OF SWITCH

Three different tests were made for applied voltages 35, 39, 41, and 43 volts rms, including the following initial conditions: 1. probable residual magnetism, but no charge on the capacitor; 2. no residual magnetism and no charge on the capacitor; and 3. probable residual magnetism and charge on the capacitor.

In tests with initial conditions 1 and 2, the switch was opened and closed 100 times. In the test with initial condition 3, it was thought that the voltage across the reactor corresponding to high or low currents of ferroresonance just before opening and then closing the switch would influence results. Therefore, a set of tests was made for each applied voltage. In the first, the voltage across the reactor corresponded to a point on the curve, a low current of ferroresonance; in the second, a high current of ferroresonance.

In these tests, no attempt was made to determine the initial value of the applied sinusoidal voltage. However, it is here concluded that for applied voltages between 25 and 35 volts, the low voltage values are more likely to occur than the high. For applied voltages between 41 and 45 volts, the high voltage values are more likely to occur than the low. The preceding conclusion is further justified in view of the fact that, inductance being a function of current, the closer saturation is approached the more predominating capacitive reactance becomes on the circuit impedance, thereby idealizing the conditions necessary to substantiate high current of ferroresonance.

Subharmonics

No sustained subharmonics were observed at any time during the tests. In the preceding section, where voltages were suddenly applied to the circuit, with and without discharging the capacitor, and with and without eliminating residual magnetism in the reactor, there was no indication that subharmonics were present, even as transients. This is not surprising, as it has been stated that subharmonics occur only at suitable values of switching angle, charge on the capacitor, and flux linkages for the necessary degree of saturation in the iron-core reactor.[9]

The circuit was closed hundreds of times in the tests described in the preceding section, but without regard to the initial value of the applied voltage. It would seem that on at least one occasion the initial value of the applied voltage would have been suitable for subharmonics. As none appeared, it can be concluded that their occurrence in the particular circuits studied would be very rare indeed, if they occurred at all. The states of ferroresonance and subharmonic oscillations are totally different phenomena unrelated in behavior.[9]

Three-Phase Circuit with Open Conductor as Example of Ferroresonant Circuit

In a recent paper,[10] tests and calculations to check tests are given for a 3-phase circuit with open conductors. The circuit considered is a 3-phase 4-wire distribution circuit, shown by a 3-line diagram in Fig. 8(A). Balanced sinusoidal voltages to ground E_a, E_b, and E_c are applied to the grounded Y-connected primary of a transformer bank, paralled by a Y-connected capacitor bank, with grounded secondary supplying a 3-phase 4-wire distribution circuit.

Let phase *a* be opened between the power source and the capacitor bank, as in Fig. 8(A).

With phase *a* at the power source as reference vector, the applied voltages E_b and E_c are

$$E_b = -\frac{1}{2}E_a - j\frac{\sqrt{3}}{2}E_a$$

$$E_c = -\frac{1}{2}E_a + j\frac{\sqrt{3}}{2}E_a$$

The voltage

$$E_c - E_b = j\sqrt{3}\,E_a$$

sends no current to ground, nor does it send any current into the open phase *a*. It can therefore be ignored in determining the voltage to ground V_a at the primary terminal of the transformer in phase *a*.

The component $-1/2E_a$, common to E_b and E_c, will send current to ground through the capacitor bank and phase-*a* primary of the transformer bank, as indicated by arrows. With no load on the secondary of phase-*a* transformer, the circuit to be studied is the simple ferroresonant circuit shown in Fig. 8(B). With load on the secondary, it is the circuit of Fig. 8(C).

In both circuits, the capacitive reactance is $-j3/2x_c$. For the case of no load on phase-*a* transformer, the circuit is similar to those studied in the section "Calculations and Test for the Same Ferroresonant Circuit" there is no resistance but that of the transformer itself. With load on phase-a transformer, as an approximation, its copper resistance and leakage reactance can be combined with the load impedance. Then, given the load impedance, the active and reactive components of load current corresponding to any assumed value of V_a (the voltage to ground at the primary of phase-a transformer) can be determined. These components can then be added to the magnetizing and power components of current in the transformer, corresponding to V_a, to give the total current entering the circuit. By assuming several values of V_a, the current corresponding to the applied voltage $-1/2E_a$, can be determined, and from it, the voltage V_a at the transformer.

There are many possible applications of the ferroresonant circuit to 3-phase circuits with open conductors, and many different methods of calculation have been given. The method of solution given in the foregoing is not necessarily the best method, but it is one which can be used. It is given here to show that the 3-phase circuit with an open conductor is a special case of the ferroresonant circuit

Recent Progress in Applying Information Theory to Digital Transmission Systems

R. FILIPOWSKY
ASSOCIATE MEMBER AIEE

Synopsis: Recent investigations, still being continued at Westinghouse, seem to indicate that careful observation of the detection theory, of the definition of digital systems, of the size of the signaling alphabet, and of the conversion process from low-pass signals to band-pass (carrier) signals may be extremely helpful for faster progress in applying information theory to digital communication systems.

MANY are convinced that information theory presented very useful results in the last decade and the author believes that many tried to apply these results in practical communication system design. The title of the paper is not meant to imply any announcement of spectacular new methods of information transmission or a presentation of final results of the author's current investigations. In this paper the author wishes to show that careful observation of all assumptions under which theoretical results have been derived does simplify and accelerate the process of applying information theory to digital communication systems. In particular the following points are stressed:

1. The detection problem for communication systems is practically in all aspects different from the detection problem in radar.

2. The term digital transmission requires an accurate definition and many different types of digital transmission systems are conceivable.

3. It seems that when using larger signal alphabets, in particular when selecting for each elementary interval in a digital system one and only one waveform out of a larger set of uniquely specified waveforms, one may arrive at more efficient digital systems, than when operating on a binary basis.

4. In truly digital systems one should specify directly carrier-band waveforms in place of a particular modulation method for carrier transmission.

With regard to item 1, the reader may remember that radar has led the way in applying the theory of optimum detection systems. Digital transmission systems have at least the pulsive operation in common with radar and it is therefore logical to expect that results of optimum radar detectors could be applied to data transmission systems.

Fig. 1 is a comparison of the most important features of a typical radar system with those of a typical communication system. Notice that practically all design parameters are of opposite character in the two cases.

Receiver and transmitter are generally at the same location in radar, but are far apart in communication links. Information is carried by the energy radiated from a communication transmitter, whereas it is generated within the channel in radar systems. Only one exactly known typical signal is transmitted in radar, but selections out of many different types of such signals, not all completely predictable, may be emitted by a communications transmitter. The detection problem in radar is primarily restricted to optimum discrimination between this one a priori known waveform and Gaussian noise. In communications, it is much more complicated, involving the error-free discrimination between all possible types of signals or the distortion-free extraction of continuous signals from noise. The time of arrival of a signal is not known in radar, because this is actually the information-carrying characteristic, which should be extracted as accurately as possible. It may be completely known in advance in some communication systems and this knowledge may be used to improve the detectibility, i.e., by clocked operation or synchronous detection. The direction of arrival is unpredictable in radar and carries another part of the wanted information. It is generally known in communication systems, except in mobile systems, where it can only be predicted by co-operation between both stations. The signal-to-noise ratio is down to the lowest possible value in radar, where it determines the

Fig. 1. Comparison of radar versus communications

range of operation. It is fairly high in many communication systems, where Gaussian circuit noise is frequently negligible against non-Gaussian external disturbances. Most radar transmitters operate intermittently, being designed for maximum peak power output, whereas most communication systems are designed for maximum average power output and operate continuously. Linearity is not a big issue in radar systems, but is of highest importance in most communication systems. Crosstalk between the channels of a multiplex system or between the elementary intervals of a digital system is a basic issue in communications, but is only a secondary problem in radar (separating closely spaced targets).

Such a large number of basic differences between radar and communications should be a warning against indiscriminate application to communication systems of those results of information theory which have been derived for the radar case. This applies particularly to the statement of radar detection theory, that the detectibility of a signal is primarily determined by the energy which a signal carries and will not be affected by the type of waveform in which this energy is being transmitted.

This statement is misleading when applied to the general model of a discrete communication system as shown in Fig. 2. A discrete information transmission system may be defined as one which transmits information by making discrete selections of predetermined signals at the transmitting side and which reconstitutes the information at the receiving side by making decisions about the type of signals, which most likely have been transmitted during a given time interval.

From this model it is seen that the main difference in a comparison with radar detection is the need to discriminate between different types of discrete signals. Thus there are two different problems which information theory has to solve for the communication system:

1. Optimum discrimination of each of the waveforms $f_1(t) \ldots f_n(t)$ against noise and disturbances, i.e., signal extraction.
2. Optimum decision between the extractor outputs, to determine which waveforms most likely have been transmitted during a given interval.

The first problem is the basic problem of radar detection theory. The second problem imposes additional requirements for specifying useful signals, and a very important one is the orthogonality requirement for admissible signals. They may all have the same energy, but good discrimination by the receiver requires that they have many different characteristics. Thus it cannot be claimed that only the signal energy determines the detectibility.

The term optimum must be explained. According to Middleton and van Meter,[1] ". . . optimization by theory can be carried out with respect to a criterion of excellence by which the performance of a reception system can be rated." (This criterion may be different for the design of radar systems and of communication systems.) "In practice, performance specifications are rarely explicit enough to fix the optimum system uniquely. More often, the designer must himself supply a definition of 'best' for the situation at hand, which is sufficiently precise to determine a unique system and which at the same time accurately reflects the given design constraints."

The foregoing definition of a discrete communication system and its detection problem still leaves the signal pattern undecided. Its only characteristic so far is that information will be exclusively expressed by selections out of predetermined waveforms.

The first specialization can be made by defining a digital system as a discrete communication system with (predeter-

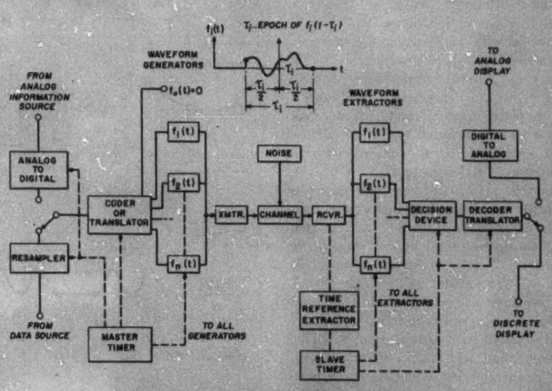

Fig. 2. Typical discrete communication system

mined) waveforms, which are limited in time and frequency. Any member $f_i(t)$ of a suitable ensemble of waveforms is a "symbol" of the signal alphabet. Each such symbol can then be nonzero only within the range

$$-\frac{T_i}{2} \leq t - \tau_i \leq +\frac{T_i}{2}$$

and must be essentially zero outside these limits. T_i is the digital interval for the symbol i and τ_i is the "epoch" of the symbol.

Following the definition of a digital system, one may further distinguish between single digital systems and multiple digital systems. The former never must send into the channel more than one signal at a time. The latter can tolerate the superposition of several signals, during the same interval or fraction of an interval. In Fig. 2 it is necessary (in single digital systems) to impose the constraint on the translator that no waveform must be triggered unless the digital interval of the previous waveform is at its end.

Any digital system may operate with the same interval length T and the same bandwidth occupancy W for all symbols, or it may have different WT values for the various symbols. The product WT may be called the signal base b of a symbol and one may speak of digital systems with uniform signal base, with staggered signal base, with weighted signal base, and with variable signal base. Systems with uniform signal base are preferred in channels with primarily Gaussian disturbances and whenever simplicity of the design is important. Staggered signal base is the same principle with a more refined matching of the signal base to the selection probability of the symbols or to the error probabilities of individual symbols in a channel with non-Gaussian disturbances. Variable signal base is applied preferably in channels with nonstationary disturbances, e.g., under jamming conditions.

Applications of information theory may now be demonstrated to the special case of a single digital system with uniform intervals. Referring to Fig. 2, a decision must be made as to how many symbols should be provided (number n), and then the actual functions $f_1(t)\ldots f_n(t)$, which all should be essentially zero outside the interval T and the frequency range W, must be prescribed.

Starting with n, the size of the signal alphabet, $f_0(t) = 0$ is included principally as an information-carrying symbol. This means that the state of nontransmitting, of no energy being submitted to the channel during specified intervals, is one of the predetermined symbols. Such a system is called a passive "$(n+1)$-ary" system, whereas a system which does not include this state may be called an active "n-ary" system. All its waveforms submit energy to the channel and thereby give an active indication to the receiver. An active system is automatically a "fail-safe" system, as any failure of the transmitter to send a symbol during any interval will be immediately registered at the receiver as a nonadmissible state. If the signal should fade during one or several intervals, the receiver will automatically locate such failures and will not mistake them for errors. This happens in the case of a passive alphabet, where a number of "space" digits would produce the same condition as an actual failure of the transmitter or a longer fade-out of the signals.

The detection problem in the passive system includes the hypothesis N, that noise alone is present during any interval. This hypothesis is nonadmissible in active systems. The passive binary system is actually the only one which can apply radar detection theory directly, with the only decision between the hypothesis N (noise alone being present) and the hypothesis SN (signal plus noise being present). The passive n-ary case has been theoretically investigated by the University of Michigan research team[2] under the assumption of a finite sampling plan and with the application to a coherent or noncoherent radar in mind, where the target is at one of a finite number of nonoverlapping positions. This case allows a decision device which can test first the hypothesis S_1N against N, then the hypothesis S_2N against N, etc., until S_nN against N, if $S_1, \ldots S_n$ are designated as the n-orthogonal signals.

The active n-ary case however excludes the hypothesis N completely and a multiple alternative decision of the hypothesis S_1N against S_2N and against all other S_iN until S_nN must be made. This decision problem has been covered by Middleton and van Meter[3] and their results may be applied for comparing the passive $(n+1)$-ary case with the active n-ary system. The above-mentioned advantage of the active system of offering automatic failure detection may be expressed by associating smaller cost $C_0^{(K)}$ with the decision that no signal was present, when actually signal K was transmitted. This cost ratio of failure against error depends on the chances for correcting failures, either by repetitions or by inspection of the output, against the chances for correcting errors, which are not yet located. It may be important to point towards the fact that in the passive binary case the energy of the only active signal can be twice the energy of either signal in the active binary case, provided both systems operate with the same average power and with equal probability for both transmission states. This power advantage of the passive system becomes smaller and smaller with increasing size of the signal alphabet. The passive $(n+1)$-ary system can use only $(n+1)/n$ times the energy per active element than the active n-ary system.

There is another subdivision of digital systems according to the size of the signal base b. If b (the WT product) is

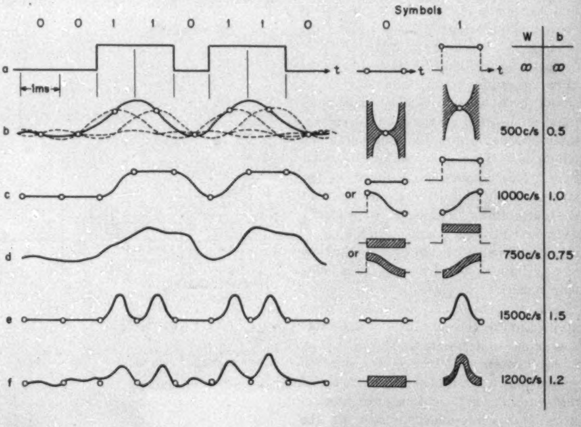

Fig. 3. Passive binary waveforms for data transmission

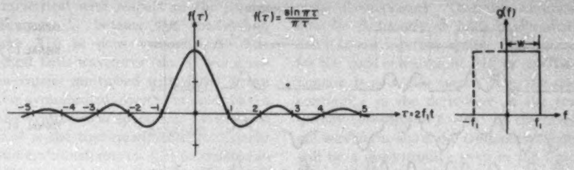

Fig. 4. Waveform (sin x)/x and its spectrum

$T=t_1=1/2f_1$, $W=f_1$, $WT=0.5$
$T_2=21/2f_1$, $W_2=f_1$, $W_2T_2=10.5$

relatively large, so that only a large number of independent samples will specify the waveform completely, statistical observations of signal and noise may be used for optimum detection systems, noiselike waveforms can be applied as signals and reliable detection of extremely weak signals in a noisy channel is possible.[3] Applying a large signal base in single digital systems leads either to a very small data rate per unit bandwidth or to extremely large alphabets.

The more frequent specification in communications calls for reliable data transmission over relatively good channels with the highest possible data rate. It is then preferably to operate with a very small signal base and possibly with large alphabets.

Before demonstrating some features of systems with larger alphabets, the author first discusses various forms of binary data transmission over a low-pass channel. It is interesting to see that ordinary teletype waveforms do not fall under the suggested definition of a digital system. Fig. 3 shows in waveform *a* a binary sequence 00110110, being represented by $f_0(t) = 0$ for 0 (space symbol) and by $f_1(t)$ = constant for *l* ("mark" symbol). This may be called a digital sequence in passive binary form and it may actually appear in this form at the output of a computor. Observe that the transitions between the two symbols are infinitely steep steps and that an infinitely wide band would be required theoretically to transmit this waveform. The signal base for the only active symbol specified would also go toward infinity.

For any practical transmission system it is desirable to arrive at the smallest possible signal base. Theoretical analysis assumes $(\sin x)/x$ sampling waveforms, whenever an attempt has to be made to specify a continuous function in terms of discrete parameters. Fig. 4 shows this waveform and its frequency spectrum. If one could define as the elementary interval the distance between any two adjacent zero crossings on either side of the center of the waveform, one would arrive at a signal base $b = 0.5$. But this definition is not in line with the one given previously for a digital system. The waveform would not be essentially zero outside such an interval. Insisting, for example, that the waveform should stay below 3% peak value everywhere outside the interval T would lead to a signal base $b = 10.5$.

Returning to Fig. 3, in waveform *b* is found the superposition of $(\sin x)/x$ signals in a passive binary system. Observe that the detection problem in this case is different, because one cannot specify the only admissible waveform over the whole interval. All that one may give to the receiver as a priori information about the waveform is its value at the center of the interval and a probability distribution for the waveform with increasing uncertainty towards the ends of the interval. At the limit, between two intervals, this uncertainty range goes even to plus and minus infinity, and this in the noiseless and distortionless case. This uncertainty results from the influence of the neighboring elements which, at least for the future, cannot be predicted. The optimum detector will in this case be a simple resampling device operating at the center of the waveform and a single threshold decider thereafter. If in addition to these theoretical arguments, the practical difficulties of generating and transmitting $(\sin x)/x$ waveforms are considered, it is evident that a signal base of 0.5 is unrealistic.

Waveform *c* shows a very economical solution, in which the whole interval is used for the transition between the two states. This transition follows purposely a positive or negative sine function from $-\pi/2$ to $+\pi/2$ with reference to the center of the waveform. It is seen that alternate transitions produce a permanent sine oscillation of a frequency equal to 1/2T. Putting this frequency at the center of the low-pass band will permit a practically distortion-free transmission of binary data at a rate equal to one bit per cycle bandwidth. The signal base *b* is unity. Observe, however, that again the waveforms $f_0(t)$ and $f_1(t)$ cannot be specified uniquely. It is seen that space can either be transmitted by a constant zero level or by a negative sine transition from peak level to zero level; similarly, for the mark symbol. Only at the end of the interval does the transmitter reach a unique state, which does not depend on the information of the previous element. This system cannot be considered as a binary digital system. It could better be designated as an analog transmission of binary information. It falls under the class of discrete communication systems, but not under the subclass of digital systems.

There is however the possibility of considering this system as a passive quaternary digital transmission system with a rate of one bit per cycle bandwidth over a low-pass channel and with four completely specified waveforms of which two represent space and two mark. The waveforms within each subset indicate also the symbol of the preceding interval, which fact may be used for error-checking procedures. This leads to the advantages of digital systems with larger signal alphabets.

Waveform *d* demonstrates the rapidly increasing uncertainty of anyone of these four waveforms, when reducing the signal base below unity. This uncertainty is again caused by intersymbol crosstalk and may be called self-noise of the system. It will be useless to reduce the signal base so much that the self-noise will approach the external noise level. The increase of signaling rate would be compensated by the increase in equivocation and the effective information transmission rate would not be increased.

Waveform *e* finally shows the only truly binary digital data transmission system on this slide. It is still a passive binary system, but a waveform $F_1(t)$ for the transmission state mark may be specified uniquely. This waveform will be submitted to a low-pass channel, whenever mark has to be transmitted, regardless of the information in any other intervals. Observe that another necessary condition for a digital system is that the selected waveforms have to start and to end all in the same transmission state, here at zero level. This will avoid any transients between the intervals, whatever combination of symbols might be selected. It may be seen that any possible transition, e.g., 00, 01, 10 and 11, can now be performed without appreciable intersymbol crosstalk. This advantage is paid for with a signal base of about 1.5, i.e., only a bit rate of about two thirds of the low-pass bandwidth can be

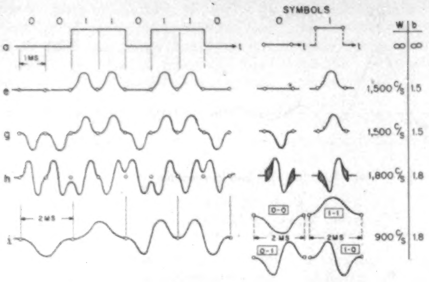

Fig. 5. Active binary and quaternary waveforms

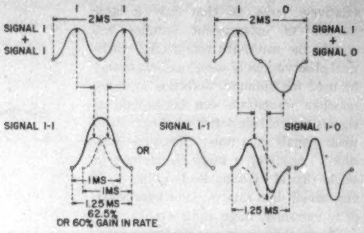

THE SIGNALS 0-0 AND 0-1 ARE FORMED BY THE NEGATIVES OF ALL THE ABOVE WAVEFORMS.

Fig. 6. Forming quaternary signals by overlapping binary signals

achieved. However the advantage of optimum detection systems is gained. Again the signal base may be reduced to about 1.2 and a certain uncertainty range due to ringing effects following the active signals may be tolerated, as demonstrated in waveform *f*.

When applying optimum detection theory to this case of very small signal base (*b* close to 1), a particular sampling plan cannot be applied, operating with $2WT$ independent samples. Middleton and van Meter[1] calculate, in Appendix I of their decision theory, the error which results from the missing contributions of samples outside the observation interval and conclude that the signal base should be at least ten to permit the neglecting of these fringe effects of a finite sampling plan. For a very small signal base, which is the rule in most communication problems, they propose an alternative procedure, leading to continuous sampling as a limiting case of discrete sampling with the number of samples increasing to infinity and the observation interval T fixed. This leads apparently to the application of matched filters or continuous cross-correlators.

So far it is seen that the desire of applying an optimum detection system leads to a definition of digital systems, which requires uniquely specified waveforms. These again require a signal base of at least 1.2. The analytical form of signals with a minimum signal base must still be defined. Since the uncertainty principle prevents the simultaneous specification of time and frequency with absolute accuracy, the limits for the bandwidth W and the time T must be defined on a tolerance basis. This can be done by insisting that the percentage of the whole energy of the waveform outside the limits W and T should be less than a certain small value, or by specifying that the maximum amplitude and maximum spectral density of the waveform outside the limits W and T should be less than a certain small fraction of the peak value of these magnitudes inside these limits.

Fig. 5 shows in line *a* the same binary sequence as in the previous slide. Below this, there is a waveform representing the passive binary system using $\cos^2$ signals. This is compared in line *g* with an active binary system, using positive and negative $\cos^2$ signals. Finally in line *h* an active binary system with waveforms of more complex character is shown. Space is represented by a waveform consisting basically of one period of a negative sine oscillation and mark is represented by a similar waveform of a positive sine oscillation.[4,5] Both require a signal base of about 1.8. Adjacent waveforms will still slightly overlap, causing a small uncertainty range at the ends of the interval. The increased signal base of this system reduces the signaling rate per unit bandwidth, but each signal now carries slightly more energy for the same peak-to-peak voltage. This increases the detectibility. These signals have also the additional advantage that they do not possess a d-c component. Thus there will be no variation of the base line depending upon the information when using these waveforms.

Combining lines *g* and *h* into a single system may be a first step toward a higher order alphabet. It is seen in line *i* how two binary elements together, i.e., binary diagrams, can form a quaternary information symbol. There are four such symbols, 00, 01, 10, and 11. Each is represented by a uniquely specified waveform. All these waveforms are now twice as long as before, require therefore only half of the bandwidth, but each waveform carries two bits of information. The quaternary system of line *i* has only half of the digital rate of the binary system of line *g*, but has the same bit rate. Its advantage is the smaller bandwidth required for the same bit rate and signal power. Smaller bandwidth means also smaller noise power, thus an improvement in input signal-to-noise ratio in the receiver.

Fig. 6 demonstrates the reason for this improvement when going to a higher order alphabet. It can be shown that the four quaternary waveforms result from superposition of the respective binary waveforms. In the quaternary system the two waveforms can be overlapped at the center of the quaternary interval and thus the quaternary interval can be reduced about five eighths of the two binary intervals. This is the real gain of the higher order alphabet. Extending this method, all 32 combinations of the five binary elements could be specified in the teletype code and form a system with an alphabet of 32 waveforms, with a correspondingly large saving in bandwidth and with considerably increased detectibility, as it would be a truly digital system. However, it would not be an optimum alphabet of waveforms.

Several publications of information theory[6] stressed the fact that an optimum set of waveforms, matched to a set of optimum signal extractors, should be orthogonal. The waveforms in such a set have to satisfy the condition

$$\int_{-T/2}^{+T/2} f_{i(t)} \times f_j dt_{(t)} = \begin{cases} 0 \text{ for } i \neq j \\ 1 \text{ for } i = j \end{cases}$$

The second condition makes the set normal.

A set of waveforms, which contains all possible waveforms of a certain class and which, can be orthogonal to each other in a given interval T, is called a closed orthogonal set. In carrier bands an attempt shall be made to find closed sets of normal and orthogonal waveforms by extending the definition to complex functions. Wiener[7] shows one possible method to derive such sets.

This leads to the last point to be mentioned. It seems that in digital transmission systems it is better to specify directly the set of waveforms within the carrier band. One may speak of pass-band waveforms and it seems that it is better to go to a larger alphabet directly within the carrier band, in place of defining a smaller alphabet within the low-pass band and transferring it by a modulation process to the carrier band.

There are good reasons for such a philosophy: it can be shown that the signal base increases when going from the low-pass band to the corresponding band-pass channel. If this is done in double side-band (DSB) modulation, the bandwidth doubles and the interval remains the same. If there is a transfer into single side-band (SSB) modulation, the bandwidth remains the same, but the interval increases. It is easy to show (see the Appendix) that the $(\sin x)/x$ waveform has in SSB an envelope with twice the distance between adjacent zero crossings, compared with the modulating low-pass waveform. Other SSB waveforms show a corresponding increase of the signal base.[8] Notwithstanding this increase of the signal base, it is found that the information-handling capacity remains constant, because in the band-pass channel there are two independent components for each waveform. They are usually called the quadrature components; using them as independent symbols doubles the size of the signal alphabet.

Fig. 7 shows as an example how one of the skew-symmetrical wave forms, which were used before in the quaternary system, is first converted to two different band-pass waveforms in DSB with suppressed carrier. Observe that the right side of the slide shows the Fourier spectrum of all these waveforms as a real function of frequency $g(f)$ ranging from $-\infty$ to $+\infty$. This completely real form of Fourier transform has been closely investigated by Hartley[9] and is called the Hartley spectrum to discriminate it from the usual complex Fourier spectrum or from the Fourier spectrum with the two real quadrature conponents (sine and cosine spectrum). It has the characteristic that symmetrical waveforms have a symmetrical spectrum and skew-symmetrical waveforms have a skew-symmetrical spectrum.

The DSB waveform, no. *2*, has a sine carrier multiplied with a skew-symmetrical waveform $A(t)$. This gives a symmetrical product function, as indicated by the actual waveform at the center. The Hartley spectrum is therefore also symmetrical with respect to $f = 0$. The two parts of the spectrum are both skew symmetrical with respect to the carrier frequency f_c, because the modulating wave $A(t)$ is skew symmetrical. The second DSB waveform (no. *3*) has a cosine carrier multiplied with $A(t)$. It is a skew-symmetrical waveform and has a skew-symmetrical spectrum. Waveform no. *4* is the time-quadrature component (Hilbert transform) of $A(t)$ modulated in DSB to a cosine carrier. The superposition of this waveform with waveform no. *2* results in the phasing method of SSB modulation. It is seen in the last line that the envelope of the resulting SSB waveform is much wider than the interval of the original function. The envelope is, as demonstrated in the Appendix of this paper, the root of the sum of the squares of the modulating function and its Hilbert transform. The SSB wave will in general have a phase-modulation term which is the arc-tangent of the quotient of the Hilbert transform over the modulating function.

It is very significant to follow this process in the Hartley spectrum. This spectrum contains the full information of each waveform, including the epoch (origin of the time scale). On each half of the spectrum of waveform no. *4* is seen the low-pass spectrum of the Hilbert transform of waveform no. *1*. This can be easily designed graphically, by merely taking the negative-half spectrum of line 1 with negative sign. If the original Hartley spectrum is neither symmetrical nor skew symmetrical, it must first be split into a symmetrical and skew-symmetrical component. Then this operation may be performed on both components and it is put together again. The reason for the wide extension of $A(t)$ in the time domain is now also seen. It is the discontinuity in the derivative of the frequency spectrum at $f = 0$. If the original waveform has a d-c component there will be a discontinuity even in the function $g(f)$ itself. Since frequency spectrum and time function are interchangeable, this spectrum may be considered as a time function, and every engineer knows that a waveform with such a sharp corner will produce a wide frequency band. Thus one understands that for SSB transmission one should use waveforms without a d-c component and possibly with horizontal tangent of the spectral curve at d-c.

However, the better approach appears to be to ask directly for the carrier-band waveform which may fit best into the given SSB and not to go through the complicated process over two modulators, one wide-band phase shifter and one combiner. If it is intended to find a waveform which would have its energy uniformly distributed over the given frequency band (SSB), one arrives at waveforms tentatively called full-band waveforms. Fig. 8 shows the two quadrature components of such full-band waveforms and their spectra. The Appendix contains the short mathematical proof of the emergence of these waveforms, by one of three modulation methods:

1. Modulation of a $(\sin x)/x$ waveform in

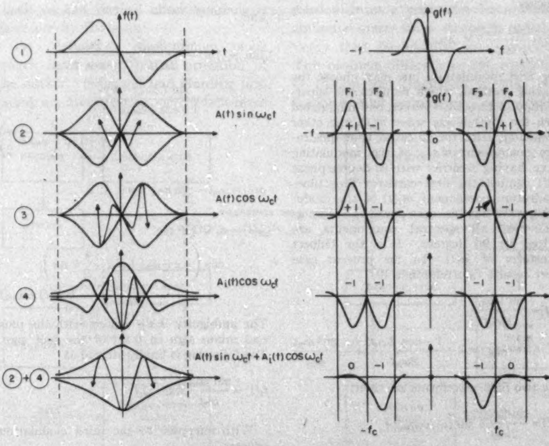

Fig. 7. SSB waveform generation and Hartley spectrum

DSB suppressed carrier modulation to a carrier at the center of the given band.

2. Modulation of a (sin $2x$)/$2x$ waveform in SSB to a carrier at the lower end of the band, selecting the upper side band in this process.

3. Modulation of a (sin $2x$)/$2x$ waveform in SSB to a carrier at the upper end of the band, selecting the lower side band.

In all three cases the result is identically the same full-band waveform with a (sin x)/x envelope and a constant instantaneous frequency at the center of the band showing no phase modulation.

At least in this case of the full-band waveforms, full identity is found between SSB and DSB waveforms. It appears therefore logical not to pay too much attention to the modulation system, but more to the carrier-band waveforms directly in digital transmission systems of high bit rate per cycle bandwidth.

Appendix

It shall be proved that the attempt to transmit a (sin $\omega_m t$)/$\omega_m t$ signal in amplitude modulation of a carrier, i.e., cos $\omega_c t$, leads identically to the same band-pass waveform (modulated signal), whether the modulation process is:

1. DSB suppressed carrier modulation, modulating ω_c with (sin $\omega_m t$)/$\omega_m t$, or
2. SSB suppressed carrier modulation of $\omega_c - \omega_m$, selecting the upper side band, and modulating with (sin $2\omega_m t$)/$2\omega_m t$, or
3. SSB suppressed carrier modulation of $\omega_c + \omega_m$, selecting the lower side band and modulating with (sin $2\omega_m t$)/$2\omega_m t$.

With reference to the first modulation process

$$f(t) = \frac{(\sin \omega_m t)}{\omega_m t} \times \sin \omega_c t$$

For SSB modulation, one may choose the phasing method, which requires the superposition of two DSB waves, one modulated with the modulating wave $m(t)$, the other modulated with the so-called time-quadrature component $m_t(t)$ of the modulating wave, having a carrier with 90-degree phase shift against the first carrier. This time-quadrature component $m_t(t)$ of the modulating wave has the same power spectrum as $m(t)$, but all spectral components are shifted for 90 degrees. It is the Hilbert transform of $m(t)$. In the present case there results (see reference 10)

$$m(t) = \frac{\sin 2\omega_m t}{2\omega_m t};$$

$$m_t(t) = -\frac{1 - \cos 2\omega_m t}{2\omega_m t} = -\frac{\sin^2 \omega_m t}{\omega_m t}$$

The two SSB waveforms are then:

$$f_1(t) = \frac{\sin 2\omega_m t}{2\omega_m t} \sin (\omega_c - \omega_m)t + \frac{1 - \cos 2\omega_m t}{2\omega_m t} \times \cos (\omega_c - \omega_m)t$$

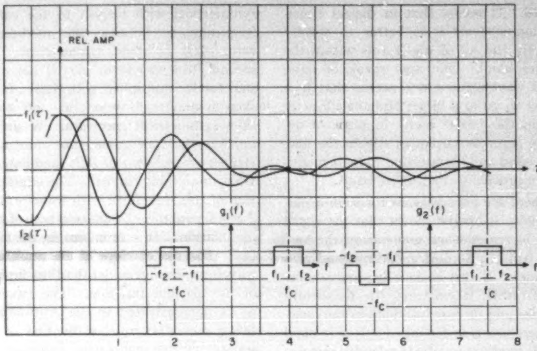

Fig. 8. Full-band waveforms

$$f_2(t) = \frac{\sin 2\omega_m t}{2\omega_m t} \sin (\omega_c + \omega_m)t - \frac{1 - \cos 2\omega_m t}{2\omega_m t} \times \cos (\omega_c + \omega_m)t$$

With reference to the second modulation process

$$f_1(t) = E_1(t) \cos [(\omega_c - \omega_m)t + \phi(t)]$$

with

$$E_1(t) = \pm\sqrt{\left(\frac{\sin 2\omega_m t}{2\omega_m t}\right)^2 + \left(\frac{1 - \cos 2\omega_m t}{2\omega_m t}\right)^2} = \pm\sqrt{\frac{2 - 2\cos 2\omega_m t}{4\omega_m{}^2 t^2}}$$

$$E_1(t) = \pm\sqrt{\frac{4 \sin^2 \omega_m t}{\omega_m{}^2 t^2}} = \frac{\sin \omega_m t}{\omega_m t}$$

and

$$\tan \phi(t) = -\frac{\sin 2\omega_m t}{2\omega_m t} \times \frac{2\omega_m t}{1 - \cos 2\omega_m t} = +\frac{\sin (2\omega_m t - \pi)}{1 + \cos (2\omega_m t - \pi)} = +\tan\left(\omega_m t - \frac{\pi}{2}\right)$$

$$\phi(t) = \omega_m t - \frac{\pi}{2} \pm n\pi, \quad n = 0, 1, 2 \ldots$$

$$f_1(t) = \pm\sqrt{E_1{}^2(t)} \times \cos\left(\omega_c t - \omega_m t + \omega_m t - \frac{\pi}{2} \pm n\pi\right) = E(t) \sin \omega_c t$$

The ambiguity $\pm n\pi$ cancels with the plus and minus sign in front of the root sign. The following is finally arrived at

$$f_1(t) = \frac{\sin \omega_m t}{\omega_m t} \times \sin \omega_c t$$

With reference to the third modulation process

$$f_2(t) = E_2(t) \cos [(\omega_c + \omega_m)t + \phi(t)]$$

$$E_2(t) = E_1(t) = \frac{\sin \omega_m t}{\omega_m t}$$

$$\tan \phi(t) = \frac{\sin 2\omega_m t}{2\omega_m t} \times \frac{2\omega_m t}{1 - \cos 2\omega_m t} = -\frac{\sin (2\omega_m t + \pi)}{1 + \cos (2\omega_m t + \pi)} = -\tan\left(\omega_m t + \frac{\pi}{2}\right)$$

$$\phi(t) = -\omega_m t - \frac{\pi}{2} \pm n\pi$$

$$f_2(t) = \pm\sqrt{E_2{}^2(t)} \times \cos\left(\omega_c t + \omega_m t - \omega_m t - \frac{\pi}{2} \pm n\pi\right) = E_1(t) \sin \omega_c t$$

Again it is seen that the ambiguity of the plus and minus signs cancels and the result is

$$f_2(t) = \frac{\sin \omega_m t}{\omega_m t} \times \sin \omega_c t = f_1(t) = f(t)$$

It may be seen also that the envelope in SSB is (sin $\omega_m t$)/$\omega_m t$, when the modulating wave is (sin $2\omega_m t$)/$2\omega_m t$. Thus the distance between any two adjacent zero crossings on the time axis doubles, when going from the modulating wave to the envelope of a SSB wave.

This proof demonstrates clearly that there is only one type of full-band wave, no matter which modulation process is chosen. However, there are the two phase-quadrature components of this wave. The same equations can be derived for

$$\frac{\sin \omega_m t}{\omega_m t} \times \cos \omega_c t$$

which is orthogonal to

$$\frac{\sin \omega_m t}{\omega_m t} \times \sin \omega_c t$$

The total band for any of these waves ranges from $\omega_c - \omega_m$ to $\omega_c + \omega_m$. The bandwidth is $2\omega_m$. Since there are two phase-quadrature components, four $\omega_m t$ orthogonal waveforms can be found again within the band $2\omega_m$ and the time T by placing the peaks of each pair of quadrature waveforms into the zeros of each other pair of such full-band waveforms.

Optimum Block Length for Data Transmission with Error Checking

F. B. WOOD
ASSOCIATE MEMBER AIEE

Synopsis: The efficiency of a block-checking system of data transmission, in which an answer-back block-checking signal is provided to acknowledge each block of characters, or to ask for a repeat if an error is detected, is investigated. Curves of data transmission efficiency, as a function of the number of characters in a message block, are shown to have sharper peaks as the distance and error probabilities are increased. For comparison, efficiency curves are plotted for a 7-bit single-error-detecting code and for a 10-bit single-error-correcting code. A family of curves of optimum block length is given for different probabilities of error and different reply times.

A BLOCK-CHECKING SYSTEM is one in which there is a periodic feedback signal which acknowledges correct receipt of the last block of *n* characters or asks for a repeat of the last block, as illustrated in Fig. 1. A block-check symbol is added after the *n*th character of the message block. It may be a simple end-of-block signal, or it may contain a parity count of the bits in particular rows of the message. To distinguish between different types of parity checks, a message can be visualized as a matrix where each column contains the bits of a single character. Then the addition of a parity bit to each character constitutes a vertical check. The block-check symbol then becomes a longitudinal check which can consist of the parity bits for each row. A special case of a block-check symbol providing a longitudinal check on the vertical check symbols is described by Barbeau.[1]

Two definitions of optimum block length have come to the attention of the author. Schatzoff and Harding proposed an investigation of the optimum block length for minimizing the undetected errors.[2] A. Cohen, in an unpublished report on transmission of punched card data over teleprinter lines, defined optimum block length as the number of characters per block which would maximize the transmission efficiency. Cohen's definition of optimum block length is used in this study.

The transmission efficiency is the time required to transmit the information bits divided by the total time required to transmit the information bits plus the time required for redundancy bits, waiting time for the answer-back signals, and the average additional time for repeated transmissions.

Bishop and Buchanan have proved a theorem that redundancy for error correction is more economical than using feedback to request a repeat when an error occurs.[3] However, automatic transmission from a computer to a remote station requires some feedback signal to verify that the channel is satisfactory. This problem differs from the conditions of Bishop and Buchanan in that both feedback and redundancy are required

$h = 1$, $p_0 = 0.0001$

so that the question is to determine the most economical ratio between redundancy and feedback for a particular set of conditions.

The effect of line failure when the automatic switching system fails to find a spare channel is not included in this analysis. For data on the probability of such events, the reader is referred to reports of Bell Telephone Laboratories.[4]

An answer-back signal is a signal sent by the receiving station to indicate acknowledgment or to request a repeat of the last block. When no errors are detected, the net information transmission rate is reduced by the time involved in coding the block-check symbol, propagation time over long line, decoding logic time, and setting of telephone line echo suppressors. When errors are detected, the net transmission rate is further reduced by the time required to repeat blocks containing errors.

Efficiency is plotted for some sample conditions of error probability and total block-check and answer-back time. A general equation for optimum block length is derived by setting the derivative of the efficiency with respect to the number of characters in a block equal to zero to obtain the condition of maximum efficiency. A set of curves is plotted for different values of reply time and character error probability.

The general equation for optimum block length reduces to Cohen's equation when the product of the block length and the probability of error are small. Sample values of optimum block length and efficiency are plotted for a range of error probabilities and transmission speeds.

The curves in this report can be used to determine the optimum block length and efficiency in practical cases by the following steps:

1. Calculate time interval per character.
2. Calculate the reply delay time interval required for the block-check and answer-back signals, and determine the number of characters which could be sent in the reply delay interval.
3. Select the curve in Fig. 2 corresponding to the number of characters determined in item 2, then determine from statistical data the probability that a character is in error. The intersection of the character error probability with the optimum block length curve corresponding to the number of characters per delay time interval gives a point which graphically yields two items:
   a. The ordinate gives the optimum block length in the number of characters per block.
   b. A projection from the point parallel to the diagonal lines shows the maximum

efficiency that can be obtained. These diagonal lines are computed for zero redundancy, so they must be multiplied by the ratio of information to total bits per character.

4. To determine the efficiency at a block length other than the optimum value use equation 13 or read the value off the efficiency curves of Figs. 3 through 6.

A sample calculation is included in Appendix III for the foregoing steps. The use of these curves permits a comparison of line rental costs with buffer storage costs. It also is of use for comparison with error correction codes. Curves for a 10-bit single-error-correcting code are included in Fig. 7 for comparison with the more frequently used 7-bit single error-detecting codes.

The derivation of the efficiency exhibits an interesting phenomenon of different probability functions for the two levels of treatment of the problem. The probability of different numbers of characters being in error within a block follows the binomial distribution. When the probability of a block of n characters being correctly transmitted is considered, the probability follows the Pascal distribution.

Efficiency of Transmission for Single Error-Detecting Code

DEFINITIONS

The efficiency of transmission E_f is defined as the time required to transmit the information bits (excluding redundancy bits) of a block of n characters without any error-detecting or error-correcting system, divided by the average time required to transmit a block of n characters with all detected errors corrected. Where T is the average time to transmit a block of n characters with all single and multicharacter errors (detectable by the code used) corrected, T_1 is the time to transmit a block without correcting the errors, and each character contains m information bits and h redundant bits, the foregoing definition results in the following:

$$E_f(h)=\left(\frac{T_1}{T}\right)\left(\frac{m}{m+h}\right)\times 100 \qquad (1)$$

Where α is the time to transmit one character, and δ is the time between the end of the last character in a record and the beginning of the first character in the next record or the next repeat transmission

$$T_1=n\alpha \qquad (2)$$

and a single block with no detected errors, but with a feedback acknowledgment signal, takes a time interval

$$T_0 = n\alpha + \delta \tag{3}$$

The average time to transmit a message block is predicted theoretically by a series of Bernoulli trials where X is the number of times a message must be sent to get a correct transmission and $E(X)$ is the expectation or average value of X, so that

$$T = T_0 E(X) \tag{4}$$

The expectation $E(X)$ is defined mathematically in Appendix I and the equation is derived there for this particular problem.

AVERAGE NUMBER OF TRANSMISSIONS PER BLOCK DUE TO INDEPENDENT STATISTICAL CHARACTER ERRORS

The symbols p_c and q_c are the probability of failure and the probability of success, respectively, of a character being transmitted correctly, where

$$q_c = 1 - p_c \tag{5}$$

It is assumed that the probability of a character being in error is based upon statistically independent events. The series of Bernoulli trials discussed in Appendix I gives the following equation for the expectation

$$E(X) = q_c^n \sum_{k=1}^{\infty} k(1-q_c^n)^{k-1} \tag{6}$$

Changing to blocks of characters, the symbols p_s and q_s are the probability of success and the probability of failure respectively, in transmitting a correct message of n characters. The relationship between the two probabilities is

$$p_s = q_c^n = (1-p_c)^n \tag{7}$$

$$q_s = 1 - p_s = (1-q_c)^n \tag{8}$$

It should be noted that p_s represents success, while p_c represents failure. This change in the role of the symbol p, when changing from characters to blocks of characters, causes the resultant equations for expectation to be in a standard form. Substituting q_c from equations 7 and 8 into equation 6 transforms the expectation into the following form:

$$E(X) = p_s \sum_{k=1}^{\infty} k q_s^{k-1} \tag{9}$$

Comparing equation 9 with the defining equation 19 in Appendix I shows that the probability function is of the form

$$P(X=k) = q_s^{k-1} p_s \tag{10}$$

which is recognized as the Pascal distribution described by Feller.[6] The terms under the summation sign of equation 9 have the form of a binomial series

$$\sum_{k=1}^{\infty} k q_s^{k-1} = (1-g_s)^{-2} \tag{11}$$

Substituting equation 11 into equation 9 results in the following value of the expectation

$$E(X) = \frac{p_s}{(1-q_s)^2} = \frac{1}{p_s} = \frac{1}{(1-p_c)^n} \tag{12}$$

The change in units used from single characters to blocks of characters results in a change from binomial distribution to the Pascal probability distribution.

EFFICIENCY

Using equations 1, 2, 3, 4, and 12 gives a transmission efficiency of

$$E_f(h) = \left(\frac{m}{m+h}\right)\frac{(1-p_c)^n}{(1+\delta/n\alpha)} \times 100 \tag{13}$$

Sample curves are plotted in Fig. 7 for $p_c = 0.001$ and $p_c = 0.00001$. The curves marked $h=1$ are for the 7-bit single-bit error-detecting code with assumption that higher order bit errors are detected by a longitudinal block check plus interlacing of characters if required to separate multiple-bit errors. Two sets of curves are shown, one for an answer-back time of three character time intervals representative of short lines, and a set for 96-character intervals, representative of a 3,000-mile nonloaded cable with echo suppressors at 2,000 bps (bits per second).

Additional curves for a range of δ/α for $p_c = 0.001$, 0.0001, and 0.00001 are plotted in Figs. 3 through 5 so that the efficiency can be interpolated from the curves in this range.

Optimum Block Length for Single-Error Detection

To obtain an equation for optimum block length, the derivative of the efficiency is taken with respect to n and set equal to zero, which gives the maxima and minima of the efficiency curves. Then, choice of the correct root corresponding to a maximum gives the optimum block length. The details of the development are given in Appendix II. Taking the positive root of equation 25 gives the optimum block length

$$\bar{n} = \sqrt{\delta/\alpha p_c}\, F(p_c, \delta/\alpha) \tag{14}$$

$$F(p_c, \delta/\alpha) = \sqrt{[1/S(p_c)] + (\delta/\alpha)p_c/4} - \sqrt{(\delta/\alpha)p_c/4} \tag{15}$$

When $p_c < 1/(100\ \delta/\alpha)$, which may also be stated as $\bar{n}p_c < 0.1$, $F(p_c, \delta/\alpha)$ approaches unity, so that the following equation has less than 5% error:

$$\bar{n}' = \sqrt{\delta/\alpha p_c} \tag{16}$$

Curves of optimum block length are plotted in Fig. 2 for different reply times (δ/α). The complete formula of equation 14 must be used for $\bar{n}p_c > 0.1$. Equation 16 can be used for $\bar{n}p_c < 0.1$.

Lines of equal efficiency have been added to Fig. 2. Substituting $\bar{n}$ in equation 13 and expanding the $(1-p_c)^n$ term in equation 13 by the binomial expansion, and dropping second-order and higher terms of p_c gives the following equation for maximum efficiency with less than 0.5% error when $\bar{n}p_c < 0.1$:

$$\bar{E}_f(h=0) = \frac{\bar{n} - \delta/\alpha}{\bar{n} + \delta/\alpha} \tag{17}$$

Efficiency for Single-Error Correction Code

For comparison of single-error detection codes ($m=6$, $h=1$) with an answer-back signal with a single-error correction ($m=6$, $h=4$) with answer-back signal, the efficiency of the error-correcting code is needed. In this sense "single error" means a single-bit error within a character. Therefore no repeats will be required for the single errors, but repeats will be asked for in the case of multiple errors detected by the addition of longitudinal block checking. Substituting the p_c'' derived in Appendix III for the 10-bit single-error correcting code of the Hamming[6] type into equation 13 gives

$$E_f(h=4) = \frac{m}{m+h} \times \frac{(1-45p_b^2(1-p_b)^8 - \ldots)^n}{(1+\delta/n\alpha)} \simeq \frac{m}{m+h}\,\frac{(1-p_c^2)^n}{(1+\delta/n\alpha)}, \text{ for } p_c \leq 0.001 \tag{18}$$

Examples of Optimum Block Length and Efficiency

Examples have been taken graphically from Fig. 7 to obtain the optimum block length and efficiency for a range of bit rates between 75 bps and 6,000 bps. These examples were based on nonloaded side circuits on a 3,000-mile 19-gage cable. These results are plotted (see Fig. 8) to show the change in optimum block length and maximum efficiency.

Curves have been plotted for lines with and without echo suppressors. Echo suppressors are used on most voice

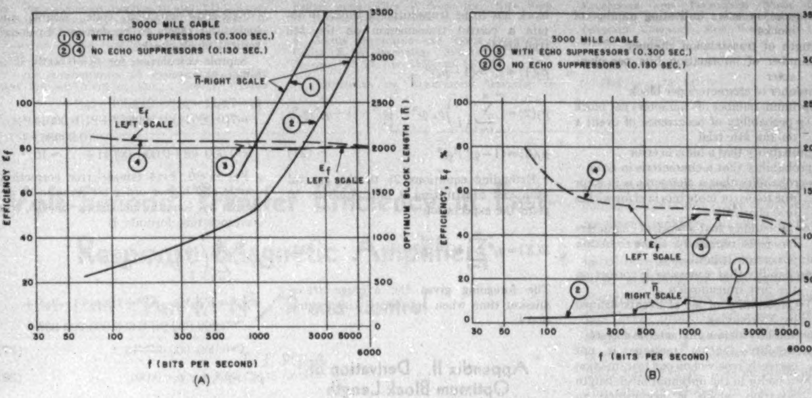

Fig. 8. Variation of optimum block length and efficiency with transmission rates:
A—$h=1$, $p_e=0.00001$ B—$h=1$, $p_e=0.001$

telephone circuits of over 500 miles. It is common to remove the echo suppressors from leased lines used solely for data transmission. A brief description of the functioning of echo suppressors may be found in a text issued by American Telephone and Telegraph Company.[7] Examination of Fig. 8 shows that the presence of echo suppressors only reduces the maximum attainable efficiency a few per cent, but their presence raises the optimum block length by as much as 50% for low-error probabilities such as $p_e=0.00001$.

This leads to the consideration of the case of a fixed buffer of less than the optimum block length. Some sample values of $\bar{n}$ and E_f are listed in Table I. If $p_e=0.001$ and $\delta/\alpha=24$, the optimum block length of $\bar{n}=130$ would give an efficiency of 69%, while the use of a buffer holding 100 characters would yield an efficiency of 62.5%. If the error probability decreases, the maximum efficiency goes up to 83% at the optimum block length of 1,300 characters. However, if the original block length of 100 characters is retained, there is still a gain of almost 7% in the efficiency without changing the buffer to the optimum block length. To decide when it is practical to adjust the buffer size to the optimum requires knowledge of buffer costs and line rental costs to determine whether the buffer costs offset the line rental savings as a result of increased transmission efficiency.

Conclusions

The importance of the optimum-block-length concept increases with an increase in any of the following parameters: 1. data transmission rate, 2. distance of transmission, and 3. probability of error. When these parameters are all low, as in the top curve ($\delta/\alpha=3$, $p_e=0.00001$) in Fig. 7, the efficiency drops only a few per cent over a range of 50 to 5,000 characters per block. As any one of these parameters increases, the curve of efficiency versus block length sharpens.

For a long-distance transmission, the increase in optimum block length indicates the need for larger buffer storage. The efficiency equation can be used in balancing the cost of the larger buffer required for use of optimum block length against possible reduced line rentals due to a higher effective data transmission rate. The calculation of optimum block length and efficiency permits a comparison of the added rental cost of the local loops to obtain complete 4-wire service with the savings from reduced size of buffer storage.

Table I. Operation at Nonoptimum Block Lengths

			Optimum		Sample Nonoptimum	
f, Bps	p_e	δ/α	$\bar{n}$	E_{max}, Per Cent	n_{no}	E_{no}, Per Cent
1,000	0.00001	24	1,300	83	100	69.1
1,000	0.0001	24	460	77.5	100	68.4
1,000	0.001	24	130	63	100	62.5

In a system where automatic communication between a computer and remote stations requires a periodic feedback signal to protect against unusual events (such as an increase in multiple errors or line failure when there are no spare channels available to the automatic switching system), the details of the situation must be examined to determine whether feedback correction of errors or error-correction by redundancy is more efficient. For some combinations of delay time (δ/α) and probability of a character being in error (p_e), the 7-bit code is more efficient, while for other combinations the 10-bit code is more efficient.

Nomenclature

a = number of bits per character
$E(X)$ = expectation of event X or the average value of X
$E_f(h)$ = transmission efficiency with h redundant bits per character
$\bar{E}_f(h)$ = maximum transmission efficiency obtainable when optimum block length is used
f = transmission rate in bps
$F(p_e,\delta/\alpha)$ = correction factor to obtain exact optimum block length from the approximate equation
h = number of redundant bits per character
i = summation index indicating number of bits or characters in error

k = summation index indicating number of blocks
l = length of transmission channel
m = number of information bits per character
$\bar{n}$ = number of characters per block
n = optimum number of characters per block
$p(x_k)$ = probability of occurrence of event x on the kth trial
p_b = probability that a bit is in error
p_c = probability that a characteris in error
p_c'' = probability that a character is in error due to two or more bits in error within one character
$p_f(k)$ = probability that a block of characters has to be repeated k times to obtain a correct transmission
p_s = probability that a message is correct on the first transmission
$P(X)$ = probability of set of events defined by X occurring
q_c = probability that a character is correct
q_s = probability that a message is not correctly received on one transmission
$S(p_c)$ = a factor in the optimum block length equation which is asymptotic to unity for small values of P_c
T = average time to transmit a block of n characters with all single and multicharacter errors corrected
T_0 = time taken to transmit a block of characters with no errors, but with reply time added to acknowledge message
T_1 = time taken to transmit a block of characters without any feedback signal
X = a set of events such as i characters in error
x_k = an event which occurs on the kth trial
α = time interval of one character
δ = reply delay time interval
δ/α = number of characters which could be transmitted during the reply delay time interval

Appendix I. Derivation of Average Number of Transmissions per Block

To obtain the average time per message T from equation 4, a formula for the expectation is derived from the following definition given by Feller.[8]

Let x be a random variable assuming value $x_1, x_2, \ldots$ with corresponding probabilities $p(x_1)p(x_2)$. The mean or expected value of x is defined by

$$E(x)=\sum_{k=1}^{\infty} x_k p(x_k) \tag{19}$$

provided that the sum converges absolutely.

The grouping in blocks of n characters sets integral values on x_k, so that $x_k=k=1, 2, 3, \ldots$ When the probability of a character being in error is independent, the binomial probability distribution applies, so

$$P\,(i \text{ characters in error})=\frac{n!}{i!(n-i)!}\,p_c{}^{0}q_c{}^{n-i} \tag{20}$$

These repeated independent trials constitute a series of Bernoulli trials as defined by Feller.[9]

Defining $p_f(k)$ as the probability that the block has to be transmitted k times, to obtain a correct transmission on the kth trial yields

$$p_f(1)=q_c{}^n=(1-p_c)^n$$

$$p_f(2)=\left[\sum_{i=1}^{n}\binom{n}{i}p_c{}^i q_c{}^{n-1}\right]q_c{}^n=(1-q_c{}^n)q_c{}^n$$

$$p_f(3)=(1-q_c{}^n)^2 q_c{}^n \tag{21}$$

Extending equations 21 to the general form and substituting it into equation 19 gives the expectation

$$E(X)=q_c{}^n\sum_{k=1}^{\infty} k(1-q_c{}^n)^{k-1} \tag{22}$$

The foregoing gives the average transmission time when substituted into equation 4.

Appendix II. Derivation of Optimum Block Length

Taking the derivative of equation 13 and setting equal to zero gives

$$\frac{dE}{dn}=\left(1+\frac{\delta/\alpha}{n}\right)^{-1}\frac{d}{dn}(1-p_c)^n+(1-p_c)^n\times \left(1+\frac{\delta/\alpha}{n}\right)^{-2}\left(\frac{\delta}{\alpha}\right)n^{-2}=0 \tag{23}$$

$$\frac{d}{dn}(1-p_c)^n=(1-p_c)^n \ln(1-p_c)$$

Let

$$S(p_c)=[-\ln(1-p_c)]/p_c=1+\frac{p_c}{2}+\frac{p_c{}^2}{3}+\ldots+\frac{p_c{}^{x-1}}{x}+\ldots \tag{24}$$

$$(\bar{n})^2+(\bar{n})(\delta/\alpha)-[(\delta/\alpha)\quad/\ln(1-p_c)]=0$$

$$\bar{n}=\frac{-(\delta/\alpha)\pm\sqrt{(\delta/\alpha)^2+4\delta/\alpha p_c S(p_c)}}{2} \tag{25}$$

Taking the positive root in equation 25 gives the optimum block length

$$\bar{n}=\sqrt{\delta/\alpha p_c}\,F(p_c,\delta/\alpha) \tag{14}$$

where $F(p_c, \delta/\alpha)$ is given by equation 15.

Appendix III. Sample Calculation and Graphical Determination of n̄ and E

Conversion of Bit Error Probability to Character Error Probability

When p_b is the probability that a bit is in error in a binary symmetric channel where bit errors are independent, and it is assumed that a block check character provides a longitudinal check on multiple bit errors, the probability of a character being in error (and being detected at the receiver) is

$$p_c=\sum_{i=1}^{7}\binom{7}{i}p_b{}^i(1-p_b)^{7-i} \tag{26}$$

Equation 26 applies for $m=6$, $h=1$ (single-error-detection code, double and higher bit errors to be detected by longitudinal block check).

Sample calculation for $p_b=0.00014$ is as follows:

$$\begin{aligned}p_c&=7p_b(1-p_b)^6+21p_b{}^2(1-p_b)^5+\ldots\\&=7(0.00014)(0.99986)^6+21(0.00014)^2\times(0.99986)^5+\ldots\\&=0.000\,98+0.000\,00041+\ldots\sim10^{-3}\end{aligned}$$

For $m=6$, $h=4$ (single-error correction, double and higher order bit error to be detected by longitudinal block check), the corresponding formula is

$$p_c''=\sum_{i=2}^{10}\binom{10}{i}p_b{}^i(1-p_b{}^i)^{10-i}$$

$$\begin{aligned}&=p_c''=45p_b{}^2(1-p_b)^8+120p_b{}^3(1-p_b)^7+\ldots\\&\simeq0.000\,000\,9+0.000\,000\,000\,336+\\&\simeq0.000\,000\,9\simeq10^{-6}\end{aligned} \tag{27}$$

$$p_c''\sim p_c{}^2,\ \text{for } p_c<0.001 \tag{28}$$

Graphical Determination of n̄ and E

Condition serial transmission, 1,000 bps, $p_c=0.0001$, $l=3{,}000$ miles.

Step 1:

$$\alpha=\frac{a}{f}=\frac{7\text{ bits per character}}{1{,}000\text{ bps}}=0.007\text{ second per character}$$

Step 2: Take $l=3{,}000$ miles, assume typical transmission line with a total of 0.300 (second) delay time for 2-way propagation and resetting of the echo suppressors. Assume that two characters are used for block-check and answer-back signals and that the logical operations can be completed within one character time, so that $\delta/\alpha=3+(0.300/0.007)=47$.

Step 3: In Fig. 2 the intersection of the curve $\delta/\alpha=47$ with $p_c=0.0001$ is marked as point A. This gives optimum block length $\bar{n}=640$, and maximum efficiency $\bar{E}=(6/7)86=74\%$.

Step 4: To determine the efficiency when 100 characters are used as the block length so that $n=100$ characters (see Fig. 4), the exact result can be obtained from equation 13 or the efficiency can be obtained by interpolating between the curves of Fig. 4. Point A for $\bar{n}=640$ and point B for $n=100$ are shown in Fig. 4. From point B it is determined the the efficiency is reduced to 57% when a block length of 100 characters is used.

Volt-Second Transfer Efficiency in Fast-Response Magnetic Amplifiers

Part I: N^2/R and Control

T. J. PULA
ASSOCIATE MEMBER AIEE

TO MAKE magnetic amplifier theory mathematically tractable, numerous analyses which have appeared in the literature employ assumptions leading to either "ampere-turn control" or "volt-second control" idealizations. While either set of assumptions leads to quite good prediction of operation for simple saturable reactors, both simplified approaches break down at several important points when extended to self-saturating magnetic amplifiers. The regions of inadequate correlation have been explored extensively in recent years in terms of ampere-turn control, especially for self-saturating amplifiers exhibiting simple time delay. However, the limitations of the more recent volt-second control approach[1,2] have received relatively little attention, especially for amplifiers exhibiting only dead-time (i.e., so-called "fast-response" amplifiers).[3–5]

The object of this paper is to extend the volt-second control approach into the region of finite signal resistance and non-ideal flux-current loops for fast-response amplifiers. In the process, certain discussions of doublet amplifiers in terms of ampere-turn control will be pursued for finite signal resistance and an attempt made to clarify the complementary relationships existing between these approaches for realistic flux-current loops. The term "doublet" is used here to describe any amplifier with a configuration of control windings which results in an exponential change in output for a step change in input.

As a result of a detailed study of the qualitative mechanics of operation of self-saturating magnetic amplifiers,[6] it has been shown that several different modes of operation are imposed upon a core material in the various types of self-saturating circuits. It is therefore quite difficult to devise one set of measurements to specify completely the significant core material parameters for these disparate circuit types. To clarify this point, each of these types will now be reviewed briefly with more specific reference to the role of the magnetic core material.

Ramey-type circuits are based on the determinate volt-second control approach and, when the required condition is met, namely $R_s \cong 0$, the operation of the amplifier is insensitive to core characteristics. However, this condition is not reasonable for a first-stage amplifier; therefore the usefulness of Ramey-type circuits is confined to second-stage amplifiers. In this application they are quite useful, especially when angle volt-second control is provided by a switching impedance in the first stage. Therefore no sophisticated core gain measurements are necessary for applications where the assumptions imposed by this type of control can be met.

Doublet circuits employ the fed back volt-seconds from the gating source to aid reset, thus increasing the obtainable volts-per-volt gain at the sacrifice of dynamic response. Their dependence on core characteristics will be discussed later with the aid of the fundamental parameter N^2/R and of incremental volts per ampere-turn gain. N^2/R is defined as the summation of the quotients of the square of the number of turns and the circuit resistance for all control circuits. As in the qualitative descriptions of reference 6, the bridge circuit will be investigated as representative of the class.

In designing a 2-stage half-wave amplifier which obtains its signal from a source with appreciable impedance, a problem common to various types of modern fast-response amplifiers presents itself. The second stage of these amplifiers, designated here as hybrid circuits, requires no close matching of core material gain characteristics, once the type of material has been properly chosen. The first stage, however, presents a problem in volt-second transfer efficiency because of the finite nature of R_s. As an application of the ideas developed in this paper, the optimization of the first stage of one amplifier in this class will be the subject of a companion paper.

Now, if ideal core material were assumed in such a first stage, determinate volt-second control would be obtained because no current would be required to flow through the reactor to accompany its change of flux, i.e., the net ampere-turns to the reactor would be zero while it was in an unsaturated state. However, since such a material does not exist, the amount of voltage which will appear at the terminals of the reactor cannot be predicted as soon as the voltage which is supplied from the signal source is known. Thus, an extra degree of freedom has been introduced because the difference between the reactor voltage and the signal voltage is a function of the resistor voltage, which in turn is equal to the signal current times the signal circuit resistance. Such a control regime has already been designated in reference 6 as "indeterminate volt-second control," wherein there is an interrelationship between the current flowing in the signal circuit and the flux reset produced. It is specifically in this area where experimental measurements of magnetic

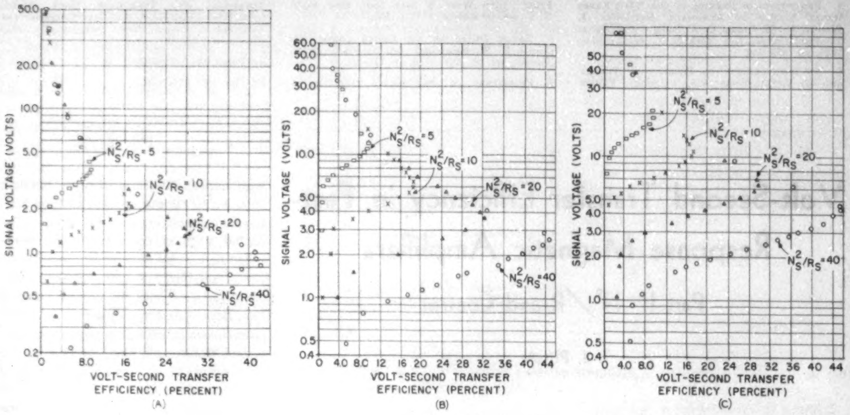

Fig. 1. Volt-second transfer efficiency for 2-mil, Hymu 80, 3/8- by 1/2- by 1/8-inch cores, N_s^2/R_s as parameter. A—$N_s=100$. B—$N_s=300$. C—$N_s=500$

core characteristics are required in the process of the design of self-saturating magnetic amplifiers. This has led some investigators,[7–9] to the extreme of simulating a control circuit current source and obtaining characteristics of the core material with a control circuit resistance approaching infinity. The disadvantage of this approach, however, is that the voltage supplied for control and, consequently the volts-per-volt gain associated with the reset obtained by this voltage, become obscure. In addition, the materials are not used with signal circuits satisfying the conditions imposed by the core measurement configurations. These considerations have led the author to pursue the investigation of indeterminate volt-second control in terms of measurements aimed at obtaining the volt-second transfer efficiency characteristics of reactors for the regime where the signal circuit resistance is finite.

Volt-Second Transfer Efficiency Measurements

The Logan (or half-wave) circuit with square-wave excitation, but without bias was chosen for these measurements. This combination is considered to be the most basic configuration: the Logan circuit because it represents the classic single-core self-saturating circuit, the square-wave excitation to minimize "back-firing," and the elimination of bias in the initial measurements to avoid coupling complications between control circuits.

To facilitate eventual correlation of these measurements with existing core evaluation technology, individual circuits from the constant-current flux-reset tester were used with minimal modifications. This test method has been thoroughly described in the literature.[7–9] The basic change made in the test method was the elimination of the inductor in each control circuit. This inductor is used in the constant-current test (along with low N and high R) to approximate $N^2/R=0$, whereas one object of the present study is to investigate the significance of N^2/R as a parameter.

The measurements consisted of recording the average voltage transferred to the reactor for various voltages applied by the signal source. These measurements, for various signal turns and signal circuit resistance values for a 2-mil Hymu *80* material, are shown in Fig. 1.

It may be seen in Fig. 1 that, for equal N^2/R values, the peak volt-second transfer efficiency values are equal but that they occur at a voltage which is higher in proportion to the number of signal turns used. This means that the accompanying average ampere-turn values are equal. When the results for equal N^2/R values are plotted not as volt-second transfer versus signal voltage but as volt-second transfer versus volts per turn applied, as shown in Fig. 2, it is found that the complete curves for equal N^2/R values coincide with each other within the accuracy of the experimental method. Similar results have been obtained for a 2-mil *50-50* NiFe material but are omitted for brevity. Therefore, even for the case of square-loop materials, where the concept of linear inductance breaks down, N^2/R remains a basic reactor parameter, and plots of volt-second transfer efficiency versus volts per turn with N^2/R as a parameter provide a basic set of core material reset characteristics.

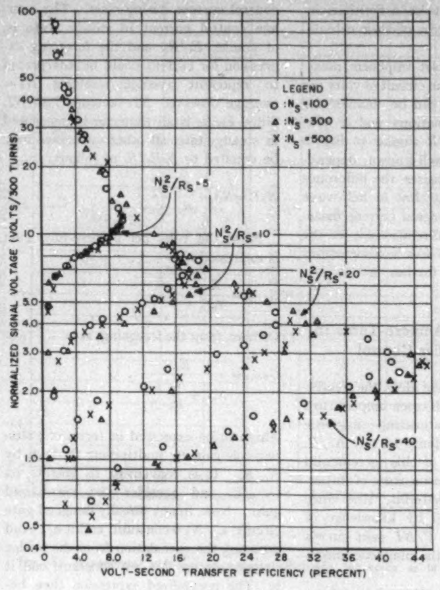
It is interesting to note from this normalization of the signal voltage that E_s/N then has the units of flux change with respect to the average core voltage (from

$\Delta\phi = \mathrm{bu}/\int e\,dt$)

It appears, then, that the obtained change of flux for each particular E_s is a constant percentage of the impressed change of flux for various combinations of N_s and R_s as long as the N^2/R values are equal. It is only when R_s approaches zero or the flux-current loop becomes ideal that a flux change is obtained which corresponds to the value which would be calculated from the normalized applied voltage.

Further Investigation of the Parameter N²/R

The emergence of N^2/R as a fundamental parameter in the volt-second transfer efficiency characteristics of the Logan circuit during reset allows a very interesting observation concerning voltage versus current in control of any magnetic amplifier. From Faraday's Law:



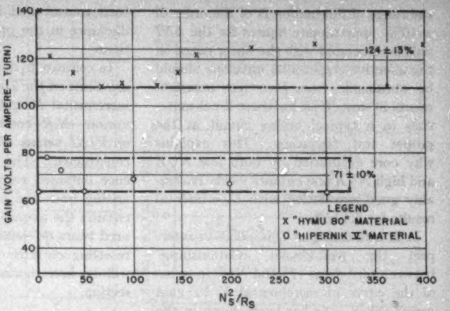


Fig. 2. (left). Normalized volt-second transfer efficiency for cores as in Fig. 1

Fig. 3 (above). Volts per ampere-turn gain versus N_s^2/R_s in bridge circuit for 2-mil, Hymu 80 and Hipernik V cores

$$e=N\frac{d\phi}{dt}$$

$$=AN\frac{d(\mu H)}{dt}$$

$$=AN\,\frac{d(\mu kNi/l)}{dt}$$

$$=\frac{kA}{l}\,N^2\,\frac{d(\mu i)}{dt}$$

$$e=\frac{kA}{l}\,N^2\mu\,\frac{di}{dt}+\frac{kA}{l}\,N^2 i\,\frac{d\mu}{dt}$$

In this equation, even though the terms $\mu\ di/dt$ and $i\ d\mu/dt$ cannot be evaluated in general, the coefficient of each of the terms equated to e contains the factor N^2. This, of course, is what would be expected from the transformer approach. However, it is only when each term of this expression is divided by $R\neq 0$ that N^2/R appears in the coefficient. And in this case it is related to e/R, a core-current expression. Therefore, as soon as the determinate volt-second control idealization is abandoned, the emergence of N^2/R as a basic parameter equivalently expresses the fact that the current accompanying reset also becomes basic.

In view of the meaning of N^2/R in a doublet amplifier, although it is true that in steady state $I_s=E_s/R_s$, the volt-seconds induced into the signal circuit during each reactor's prefiring interval may be considered to contribute to reset. In fact, for high N^2/R the induced volt-second area on any reset half-cycle greatly exceeds the volt-seconds providedby $E_s\times \Delta t$. This fact has led to many attempts to relate the incremental ampere-turns associated with the carrier frequency sinusoidal voltage loop to the incremental resetting ampere-turns required for control. Care must be exercised in this regard, however, because a large number of half-cycles is required to obtain the new steady-state condition and the basic function of E_s is gradually to shift the steady-state operating point of the transient ratcheting process, as discussed in reference 6. Thus, on individual reset half-cycles during the transient, the maximum gating ampere-turn value varies for firing angles greater than 90 degrees, and an altered domain configuration at the beginning of reset should be expected. Therefore the incremental resetting ampere-turns cannot be associated in a straightforward way with the carrier frequency sinusoidal voltage loop for large changes of output. For this reason it is helpful to visualize an effective trapezoidal envelope similar to that developed in the discussion of the Logan circuit in reference 6.

In contrast, for low N^2/R, the volt-seconds induced into the control circuit have a negligible effect. Reset is produced by control alone. Assuming for definiteness that the bridge circuit is biased to cutoff, the ΔNI product required from the signal source is that value corresponding to the maximum flux excursion of the effective trapezoidal envelope. It should be noted for this case that this ΔNI product cannot be associated with any single flux current loop.

To produce the required change in flux for the low N^2/R case, a corresponding average $d\phi/dt$ must be obtained so that the required $\Delta\phi$ is obtained in 1/2 cycle of the carrier frequency. This is the same average $d\phi/dt$ represented by the carrier frequency voltage source loop and might lead to a prediction of comparable ΔNI products. However, the losses associated with the flux change (and therefore the ΔNI required) are a function of the instantaneous $d\phi/dt$ rather than the average $d\phi/dt$. Therefore, it cannot be stated a priori that the V/NI_{avg} gain will be strictly independent of N^2/R. However, there is no straightforward relationship showing variation of V/NI gain with N^2/R.

Measurements of incremental volts per ampere-turn gain versus N^2/R for bridge circuits constructed from Hymu *80* and Hipernik *V* materials were obtained and the incremental volts per ampere-turn gain versus N^2/R plotted in Fig. 3. Although some functional relationship exists in these curves, there is no large magnitude trend. Furthermore, since the range of fluctuation is of the order of ±10%, approximate figures for the ΔNI values associated with the linear range on the effective trapezoidal envelope should be obtainable from core test measurements at any N^2/R for these 2-mil materials in a typical bridge circuit at the proper test frequency. This explains why core evaluation by both low N^2/R and high N^2/R test circuits yields reasonably good correlation with experimental results for doublets.[7–10]

It is interesting at this point to interpret the well-known relationship,[11] between time delay (T) and N^2/R in terms of the curve of incremental V/NI gain versus N^2/R. As has been shown in the plot of Fig. 3, the ΔNI required for full ΔE_L over the linear range is, to a good approximation, independent of N^2/R. Now, since in steady state, $\Delta E_s = \Delta I_s R_s$, the $\Delta E_L/\Delta E_s$ ratio reflects the $1/R_s$ $(\Delta E_L/\Delta I_s)$ ratio. (This is true because, although R_s can be any finite value in this discussion, it is held fixed at one setting while any particular $\Delta E_L/E_s$ curve is taken.) Now, this $\Delta E_L/\Delta I_s$ ratio is finite only if the left flank of the effective trapezoidal envelope is not perfectly vertical. Correspondingly, therefore, the Harder and Horton expression for time delay

$$T = \frac{1}{2f_0}\,\frac{\Delta E_L}{\Delta E_s}\,\frac{N_s}{N_L}$$

f_0 = supply frequency

which may now be written as

$$T = \frac{1}{2f_0}\,\frac{N_s}{N_L}\,\frac{1}{R_s}\,\frac{\Delta E_L}{\Delta I_s}$$

or

$$T = k\,\frac{\Delta E_L}{\Delta I_s}$$

for any particular amplifier, yields a finite value for the time constant only if the left flank of the effective trapezoidal envelope is nonvertical.

The central point to be emphasized here is that this ΔI_s, associated with the change of E_L requires a considerable number of half-cycles of the supply frequency to be realized. Thus, although concepts of incremental volt-second transfer are applicable in each reset half-cycle, control is produced only by a series of such increments in conjunction with gradually shifting boundary conditions, i.e., an integrated volt-second transfer mechanism. In the opinion of the author, it was largely this integration process and the associated constancy of the $\Delta N_s I_s$ which led many early writers to discuss doublet amplifiers in terms of ampere-turn control and invoke a fictitious inductance in the process of their calculations.

In contrast to doublet amplifiers, measurements on the Logan circuit of volts per incremental NI gain can be obtained for various N,R combinations and a plot of V/NI versus N^2/R similar to Fig. 3 constructed. The well-known dependence obtained emphasizes the difference arising from the fact that in half-wave circuits the average signal current measured bears no general relationship to the resetting current. These considerations will be investigated further in the next section.

Volt-Seconds and Ampere-Turns in Magnetic Amplifier Control

If core materials were ideal, the steady-state incremental volts per ampere-turn gain of any self-saturating magnetic amplifier would be infinite for any N^2/R. Therefore the value of this incremental V/NI gain provides a measure of imperfection in the core material. And since designs are optimized by knowledge of imperfections, these V/NI gain curves form a basic link in the magnetic amplifier design art.

It is interesting to attempt to extend the idea of constant incremental ampere-turns to a fast-response indeterminate volt-second controlled stage where the average incremental NI measured in the signal circuit cannot be directly associated with reset, since reset is obtained only on alternate half-cycles. (In such cases the induced current from E_{ac} during the prefiring portion of a gating half-cycle does not produce any core reset as in the bridge circuit.)

For this purpose, consider the governing equations of the Logan circuit during a reset half-cycle. From Kirchhoff's voltage law

$$E_c = i_c R_c + e_{\text{core}}$$

Now, by basic magnetic-amplifier design, for complete reset

$$\bar{e}_{\text{core}} = \frac{N_c}{N_L}\,\bar{e}_{ac}$$

Therefore, in terms of average values for complete reset

$$\bar{\imath}_c = \frac{E_c - (N_c/N_L)\bar{e}_{ac}}{R_c}$$

Multiplying through by N_c yields

$$N_c\bar{\imath}_c = \frac{N_cE_c - (N_c^2/N_L)\bar{e}_{ac}}{R_c}$$

Note carefully here that $\bar{\imath}_c$ is not the average control current but the average control current during reset. The average control current in steady state is, of course, E_c/R_c, and the foregoing expression for current could be interpreted to represent average resetting NI = average observed NI − average loss NI. Since E_c/R_c is all that can be measured in steady state, all other quantities may be equated to N_cE_c/R_c as follows:

$$N_cI_c = N_c\bar{\imath}_c + \frac{N_c^2}{R_c}\,\frac{\bar{e}_{ac}}{N_L}$$

Now, the volts per ampere-turn gain is expressed as

$$G_{v/NI} = \frac{E_0}{N_cI_c}$$

Or here, from the foregoing, as

$$G_{v/NI} = \frac{E_0}{N_c\bar{\imath}_c + \dfrac{N_c^2}{R_c}\,\dfrac{\bar{e}_{ac}}{N_L}}$$

This can be expressed in terms of volts-per-volt gain by multiplying through by N_c/R_c. It is convenient to operate on $G_{v/v}/E_0$ and consider the normalized gain. Now, in any already designed gate circuit, $\bar{e}_{ac}/N_L$ = constant, call it a. And pursuing the speculation from the bridge circuit, assume $N_c\bar{\imath}_c$ = a constant, call it b. The normalized expression then becomes

$$\frac{G_{v/v}}{E_0} = \frac{N_c}{bR_c + aN_c^2}$$

Taking the partial derivative of this expression with respect to N_c for R_c fixed $\neq 0$, equating to zero, and solving for N_c^2/R_c

$$\frac{N_c^2}{R_c} = b/a$$

This then represents the value of N_c^2/R_c which will maximize the volts-per-volt gain. Substituting back this value for N_c^2/R_c yields

$$G_{v/NI} = E_0/2b$$

Therefore, for maximum volts-per-volt gain with R_c fixed $\neq 0$, a value of N^2/R which makes the V/NI gain equal to 1/2 $(G_{v/NI})_0$ should be chosen.

In terms of incremental volt-second transfer efficiency, therefore, the N_c^2/R_c which gives $G_{v/NI} = 1/2$ $(G_{v/NI})_0$ gives maximum $G_{v/v}$ when N is varied for fixed $R_c \neq 0$. But this result is obtained by assuming the product (N_ci_c) equal to a constant for a given material configuration and frequency for full linear ΔE_0. Therefore, for maximum $G_{v/v}$ for fixed R_c this corresponds to $I_c = 2\bar{\imath}_c$. And in steady state, $I_c = E_c/R_c$. Therefore $i_cR_c = E_c/2$. In other words, maxi-

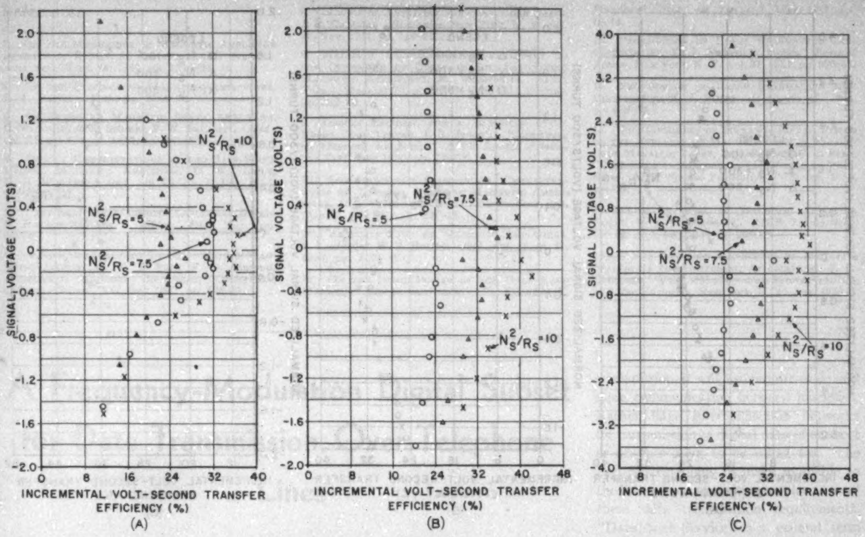

Fig. 4. Incremental volt-second transfer efficiency for cores as in Fig. 1, with bias. A—N_c=100. B—N_c=300. C—N_c=500

mum $G_{v/v}$ is obtained for fixed $R_c \neq 0$ when, in terms of average values, half the voltage during reset is allowed to appear across R_c. But this is just what is obtained with an incremental volt-second transfer efficiency of 50%. This result has been obtained recently[4,12] without explicit attention to average values.

It is very interesting to attack this same derivation by applying directly the observation for doublets that the average $(d\phi/dt)$ must be equal for all N^2/R values. The governing equations for the Logan circuit during reset can be manipulated as follows:

$$E_c = i_c R_c + N_c \frac{d\phi}{dt}$$

Multiplying through by N_c/R_c and rearranging to isolate the resetting mmf (magnetomotive force) yields

$$N_c i_c = \frac{N_c}{R_c} E_c - (N_c^2/R_c)\frac{d\phi}{dt}$$

Now, consider the value of N_c which will maximize this mmf for complete reset. For constant $R_c \neq 0$, by partial differentiation with respect to N_c and equating to zero,

$$\frac{E_c}{R_c} - \frac{2N_c}{R_c}\frac{d\phi}{dt} - \frac{N_c^2}{R_c}\frac{\partial(d\phi/dt)}{\partial N_c} = 0$$

Considering this expression in terms of average values and tentatively extending the conclusion from doublets, i.e., $\overline{(d\phi/dt)}$ = constant, yields

$$E_c = 2N_c\left(\overline{\frac{d\phi}{dt}}\right)$$

Therefore, for constant $R_c \neq 0$, the average net mmf during reset is maximized by choosing N_c so that

$$\frac{N_c\left(\overline{\frac{d\phi}{dt}}\right)}{E_c} = 0.50$$

But this is equivalent to obtaining a volt-second transfer ratio (VSTR) of 50%, since

$$\text{VSTR} = \frac{\int_0^{T/2} e_{\text{core}}\,dt}{E_c \times T/2}$$

$$\text{VSTR} = \bar{e}_{\text{core}} \times \frac{1}{E_c}$$

and

$$\bar{e}_{\text{core}} \equiv N_c\left(\overline{\frac{d\phi}{dt}}\right)$$

Therefore, both the ampere-turn control approach assumption of $N_c\bar{i}_c$ = constant for complete reset and the volt-second control approach assumption of $\overline{(d\phi/dt)}$ = constant for complete reset both yield the same result of adjusting N_c, for fixed $R_c \neq 0$, to obtain a volt-second transfer ratio of 50%.

Apart from the usefulness of this conclusion in optimizing the volts-per-volt gain of certain types of self-saturating magnetic amplifiers, the correspondence of both ampere-turn and volt-second approaches sheds considerable light on the fundamental physical processes in control. In the first place, analyses using practical core materials cannot neglect the incremental ampere-turns required to produce a change of flux level and, contrariwise, the choice of parameters which maximizes the average resetting magnetomotive force at the same time produces the optimum magnitude of this $\overline{(d\phi/dt)}$, and consequently the maximum reset with the associated maximum volts-per-volt gain.

These complementary assumptions (i.e., $N\bar{i}_c$ = constant and $\overline{(d\phi/dt)}$ = constant) are quite reasonable in terms of modern domain theory because they imply that for a given average incremental H field (proportional to $\Delta N\bar{i}_c$), the same average domain wall velocity, proportional to $\overline{(d\phi/dt)}$, is obtained regardless of how this configuration was produced in the circuit. And it has been shown[12-16]

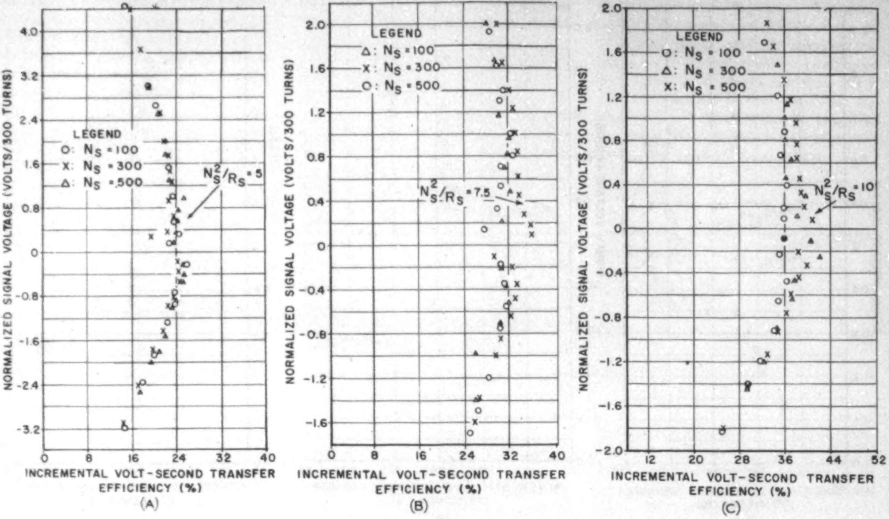

Fig. 5. Normalized incremental volt-second transfer efficiency for cores as in Fig. 1, with bias

that this proportionality constitutes one of the basic relationships in domain wall dynamics. The significance of these conclusions in terms of incremental volt-second transfer efficiency measurements will be investigated in the following section.

Incremental Volt-Second Transfer Efficiency Measurements

In the volt-second transfer efficiency curves of Fig. 2 the volt-second transfer efficiency versus volts per turn applied is quite variable and, as would be expected, this produces a quite nonlinear volts-per-volt amplifier gain curve. For this reason, it is general design practice to provide some sort of bias in order to shift the operating point of the magnetic reactor to a more nearly linear portion. In terms of this approach, therefore, information concerning the incremental volt-second transfer efficiency of resetting reactors must be obtained. This can be done by biasing the Logan circuit to half of maximum volt-second transfer, with a separate winding having a negligible N^2/R.

For the measurements obtained with the special test circuit used, the N^2/R of the bias circuit was adjusted to approximately 0.30. Later measurements will show that the fundamental nature of N^2/R as a parameter is not jeopardized by this procedure, nor is the character of volts per turn as a normalized signal. When measurements of incremental volt-second transfer efficiency versus signal voltage are plotted, as in Fig. 4, the curves are seen to be symmetrical and considerably more vertical than without bias. Furthermore, when these curves are replotted versus volts per turn applied as in Fig. 5, the curves for a particular N^2/R show strong correlation, i.e., the incremental volt-second transfer efficiency remains substantially constant over a considerable swing of the input signal and an incremental efficiency can be associated with each N^2/R. This material characteristic is really the source of the linear portion of the volts per volt or volts per incremental ampere-turn gain curve of self-saturating magnetic amplifiers.

Now, as a series of curves of incremental volt-second transfer efficiency versus volts per turn applied is obtained, it is seen that the curves show a shift in percentage with N^2/R. A fundamental characteristic of a particular core configuration at a given frequency, therefore, is the N^2/R value corresponding to a particular incremental volt-second transfer efficiency percentage. In a companion paper tentatively titled "Part II: N^2/R as a Design Parameter," it will be shown that for a very useful type of fast-response amplifier the volts-per-volt gain can be optimized by choosing an effective incremental volt-second transfer efficiency of 50% for a fixed value of control circuit resistance other than zero. In other words, in a particular design for such an amplifier, when signal resistance is fixed at some allowable minimum, these plots can be employed to pick the optimum value of N_s, i.e., to pick the value of signal turns to yield 50% effective incremental volt-second transfer efficiency for that resistance and, consequently, to yield the maximum volts-per-volt gain in the amplifier.

Conclusions

The volt-second control approach has been extended to consider a finite control circuit resistance and nonideal core characteristics by obtaining volt-second transfer efficiency characteristics for reactors composed of square-loop magnetic materials. The nature of N^2/R as a basic reactor parameter has been demonstrated experimentally and this knowledge used in deriving expressions which indicate the complementary relationship existing between volt-seconds and ampere-turns in magnetic amplifier control.

A Frequency-Modulation Digital Subset for Data Transmission Over Telephone Lines

LAURANCE A. WEBER
MEMBER AIEE

Synopsis: Modern business is embracing automation. In the business field, automation is often termed integrated data processing (IDP). This involves the use of large-scale digital computers as fundamental elements in the bookkeeping and routine activities of business. The communication system role in IDP is to transmit digital data from one location to another. This may involve sending data from subsidiary centers to a processing center or it may involve transmission of data from the central location to other business offices. The telephone companies are especially well fitted to handle the needs of business customers in this field because of their well-developed wire line distribution networks. The Bell System expects to offer digital transmission services over normal telephone lines. This is the Bell System Dataphone Service.

As one of a line of instrumentalities for the Dataphone service, an FM (frequency-modulation) digital subset has been developed for transmitting sequential binary data over telephone lines. This equipment accepts sequential binary data from customers' machines at rates up to about 1,000 bps (bits per second), modulates this base band signal to FM signals appropriate to the bandwidth available on telephone channels, transmits this signal to the line, detects the signal at the receiving end, and reconverts the line signals to d-c serialized binary data of the same form as originally presented.

This paper indicates some of the design problems for such transmitting-receiving equipment and also indicates some of the possibilities which appear to be forthcoming in the Dataphone service. At present a limited number of circuits of the type to be described are being used by various Bell System companies to test and assess the features and facilities which will be needed by Bell System customers for the Dataphone service.

The FM modulator-demodulator employed in the digital subset is fully transistorized. It represents a first-order effort at the solution of the transmission problem of sending data over switched telephone connections. Since the binary information rate (up to about 1,000 bps) is comparable to the transmission carrier frequency, the detecting means must be able to reconstruct the digital data even when there are only a few cycles of carrier signal per bit. The demodulator uses the principle of zero-crossing detection to accomplish this. The digital subset has been designed for maximum flexibility in working with existing input-output devices. Flexibility has been included to allow use with equipment still in the preliminary development stage.

The digital subset is arranged so that a Dataphone station may be operated remotely on an unattended basis in conjunction with certain auxiliary apparatus. This will allow pickup and delivery of data to remote stations during nonbusiness hours.

THE DEMAND of modern business for IDP will place a large burden on the communication companies. It is obvious in this age of decentralization that, just as business requires vast amounts of communication for voice transmission, it will also require more and more communication between machines. Rather large interconnection networks for transmission of digital data of one sort or another seem to be called for. The Bell System plans to make available to the business community a service to meet these data transmission requirements. "Dataphone Service" is a general term which describes the transmission of data over telephone voice facilities. The telephone companies are uniquely able to provide service of this type because of the general availability of voice channels and the well-developed methods of interconnecting customers on a demand-real-time basis. At present, it appears that most of the data transmission requirements that businesses have will be met with the use of normal telephone voice channel bandwidths.

This paper will discuss some of the general problems involved in data transmission over telephone voice facilities. It will also describe, as one of the instrumentalities of the Dataphone service, an FM digital subset which has been designed to accept serialized d-c binary input information at bit rates up to about 1,000 bps and to transmit this information at appropriate carrier frequencies over a regular telephone channel. In the future it may turn out that the amount of data which must be sent between two points in an IDP network may

involve bit rates higher than this. This will require more efficient utilization of the voice bandwidth by more sophisticated coding or modulation schemes or the application of broader bandwidths to the problem. Some interesting techniques toward this end have been reported.[1,2]

The Data Transmission Problem

The data transmission problem with higher bit rates and the use of voice-band channels is in a sense merely an extrapolation of the familiar telegraph transmission problem which has received much attention over the years. Theory states that the channel capacity C, in the Shannon sense, is given by

$$C=f_0 \log_2\left(1+\frac{S}{N}\right) \quad \text{bps} \qquad (1)$$

where f_0 = the bandwidth in cps (cycles per second) and S/N is the power signal-to-noise ratio. For bandwidths of, say, 2,500 cps and S/N ratios of, say, about 20 db (decibels) or so, the channel capacity works out to be in the order of about 15,000 bps. It is also known that one should be able to signal up to the channel capacity in equation 1 with an arbitrarily small error rate by using suitably selected coding. However, when the communication channel is a telephone line, several factors compel constraint to a practical rate of perhaps a tenth or a little more of the theoretical capacity. In the first place, the amplitude-phase characteristics of the channels differ from that assumed by the theory; delay distortion at the extremes of the band, for example, must be considered. Secondly, noise, particularly of the impulsive type, and other momentary disturbances often cause difficulty which is most severe at the higher bit rates. There are also net loss changes in the circuits. These are all different from the simple Gaussian interference assumed in the derivation of equation 1. Maximum exploitation of the capacity relies on coding techniques which usually result in prohibitive terminal costs, at least for general use. A further problem is introduced when data channels are to be set up on a demand basis, since tandem combinations of all the many differing types of telephone transmission facilities will be encountered. For an excellent discussion of the general problem refer to the paper by Mertz and Mitchell;[3] their paper indicates the possibilities of amplitude modulation vestigial sideband and FM for high-speed data transmission over message facilities. The FM digital subset, to be described in this paper, was built to exploit this method of transmission.

The Digital Subset

The subset makes it possible for business machines or computers to "talk" to each other over telephone lines. The subset is arranged for alternate use of the voice line for normal speech communication and for data. The subset accepts binary digital information from the customer's equipment, converts it to suitable frequency-modulated voice tones for transmission over the channel, recovers the binary data signals at the receiving station, and passes this information reshaped but not retimed to the receiving customer's data equipment.

The basic transmission scheme is simple frequency shift carrier operation. When a binary 1 or "mark" is presented to the subset a voice frequency F_1 is transmitted;

Fig. 3. Modes of operation: D, LSD, and TTX

when a binary 0 or "space" is presented another voice frequency F_2 is transmitted. Selection of suitable frequencies F_1 and F_2 must take into consideration bandwidth restrictions on the channel, bit rates expected, and possible interference with signaling circuits connected to toll channels. An appropriate set of frequencies for use where the most restrictive narrow-band voice channels may be encountered is

$F_1 = 900$ cps

$F_2 = 1{,}400$ cps

If the subset is used with private line circuits where the bandwidth is less restrictive (say, 400 to 2,500 cps), then an appropriate set of frequencies is

$F_1 = 1{,}100$ cps

$F_2 = 1{,}900$ cps

Using the higher frequencies will, of course, allow higher bit rates. The subset allows individual adjustment of these frequencies for optimum operation over the facility used.

It is proposed to use the digital subset in the Dataphone service at a maximum speed of 600 bps. For data transmission over private-line channels the speed will be 750 bps. A higher rate of 1,000 bps may be obtained by special delay equalization of the private-line channel.

Fig. 1 shows front and rear views of initial models of the digital subset. The electronic circuitry is entirely transistorized. Fig. 2 shows a block diagram of the digital subset from which the various equipment elements in the photographs can be identified. The modulator takes the binary data from the data-producing machine and modulates it to frequencies F_1 and F_2 for transmission to the line; the demodulator receives signals from the line, limits and shapes them, and passes a detected signal to the associated data-reproducing machine in the form of serialized binary d-c pulses; the control circuit is a switching unit to allow association of a number of different data-producing reproducing equipments with the modulator and demodulator; the telephone set allows alternate use of the voice facility for speech purposes and data, and also controls the selection of the connected data equipment; the power supply services the modest power requirements of the transistor circuitry and the relays in the control panel.

Digital Subset Modes of Operation

Before discussing the operation of the transmission part of the digital subset, it will be convenient to present a general idea of the control function design. Three basic modes of operation are provided for; these are selected by operation of push buttons on the telephone set associated with the digital subset.

A teletypewriter mode (TTX) allows transmission from and to a 100-wpm (words per minute) *28*-type teletypewriter. In this mode appropriate connections are made from the modulator and demodulator to the *28* teletypewriter, and a low-pass filter suited to this low speed of transmission is switched into the demodulator. The TTX mode, of course, does not exploit the full speed capability of the voice channel. Its provision, however, is useful in a number of respects. Many business routines are now built around standard teletypewriter procedures. Thus, the digital subset may be used in basic business programs without essential changes in these programs. In addition, the unattended features (to be discussed in the following) of the digital subset rely on the remote-control signals available from a *28* teletypewriter. These features will be discussed. Inclusion of this mode of operation in the first digital subsets will also lead to an answer to the question, "Is this mode of operation useful to the business community?"

A low-speed data mode of operation (LSD) is also provided in the digital subset. This mode allows transmission at speeds up to about 180 bps. It is included to allow operation with automatic tape transmission machines such as the Commercial Controls Corporation Teledata machine. This mode is selected by operation of the LO SP DATA button on the telephone set. Operation of this button connects the data machine to the digital subset and selects the appropriate filter in the demodulator.

A high-speed data *D* mode of operation is also provided. Here the maximum capability of the digital subset is used. This mode is obtained by operation of the DATA button on the telephone set. As far as the characteristic distortion of the modulator-demodulator is concerned, bit rates considerably higher than 1,000 bps are possible in this mode of operation. However, the delay characteristics of speech channels generally limit the bit rate to about 1,000 bps. The higher rates are accompanied by increasingly large distortions so that the maximum capability is obtainable only by the use of exceedingly stable auxiliary synchronizing units. This type of synchronizing unit integrates over several transitions and provides a clock signal, so that the received signal is sampled precisely in the center of a bit. In this way transmission is satisfactory even where transmission distortion is rather severe.

Where narrow speech channels may be encountered (for example, "emergency bank" circuits) bit rates of 600 bps are realizable with distortion low enough so that simple synchronization such as start-stop may be employed.

It is expected that a number of different manufacturers' equipment will be usable with the digital subset in the higher speed data mode. A representative data

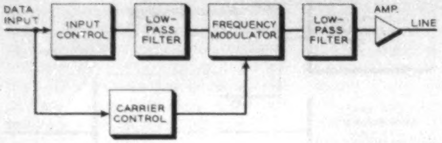

Fig. 4. Modulator block diagram

machine used in most of the early tests is a Teletype Corporation 600-word-per-minute reader and punch, using standard 5-level teletype tape. It is in this mode of operation, probably, that the largest economic advantage of Dataphone operation will be evident.

Fig. 3 shows in block form the three basic modes of operation of the digital subset. The input and output requirements in each of the modes are described in the next section.

Input and Output Signals

In the TTX and LSD modes of operation the digital subset expects to work with telegraph-type equipment. Therefore the subset is arranged to accept the usual contact closures and opens for mark and space signals. Information from the digital subset to the data machines is in the form of loop closures and opens; spacing, 0 milliamperes, marking, 20 milliamperes into a *255A* relay or equivalent.

For the D mode of operation either polar or neutral signals can be received and sent. With neutral pulsing the digital subset accepts pulses of 0 volts marking and −12 volts spacing into an input impedance of 2,200 ohms. It provides an output from the demodulator of a similar nature; marking 0 volts, spacing −12 volts into an impedance of 2,200 ohms. With polar pulsing the subset accepts pulses of +6 volts marking and −6 volts spacing into the same input impedance. The demodulator output is +6 volts marking and −6 volts spacing into an impedance of 800 ohms.

Digital Subset Modulator

A block diagram of the modulator is shown in Fig. 4. The input binary signal from the data-producing equipment is fed through an input control block where the various inputs are standardized. Following this, a low-pass shaping filter is introduced to shape the mark-space transitions to obtain proper keying of the frequency modulator. The output of the shaping filter is a voltage of one value for marking and another for spacing. This is fed to a 6-transistor multivibrator frequency modulator. This is a free-running Eccles-Jordan type of flip-flop arranged so that the frequency is governed by the d-c voltage fed to it from the low-pass filter. The circuit of the modulator is shown schematically in Fig. 5.

The stage consists of the basic flip-flop transistors *Q7* and *Q8* and a pair of symmetric interconnecting circuits. One interconnecting circuit of this pair includes buffer transistor *Q6*, trigger control transistor *Q12*, the trigger-timing circuit *R30* and *C6*, and coupling diode *CR2*. The other circuit of the pair includes transistors *Q9* and *Q11*, resistance-capacitance timing circuit *R29* and *C5*, and coupling diode *CR1*. A half-cycle of the operation of the circuit will be described.

Assume that transistors *Q7* and *Q12* are on. Diodes *CR1* and *CR2* are reverse-biased. Timing capacitor *C5* has, during the previous half-cycle been charged to the ON collector potential of *Q11*. This capacitor will discharge through *R29* from the ON potential of *Q11* toward the less positive keying voltage delivered from the input control circuit. Capacitor *C5* discharges until it reaches a voltage which forward-biases diode *CR1*. The more negative the keying voltage, the sooner this will occur, and the higher the frequency of the circuit. When *CR1* conducts, it conducts current away from the base of *Q7* and turns it off. When *Q7* turns off, the collector base cross coupling to *Q8* turns that transistor on. The collector drop in *Q8* is transmitted through emitter follower *Q9* to the base of *Q11*, turning it on. Transistor *Q11* provides a low-resistance charging path for *C5* which

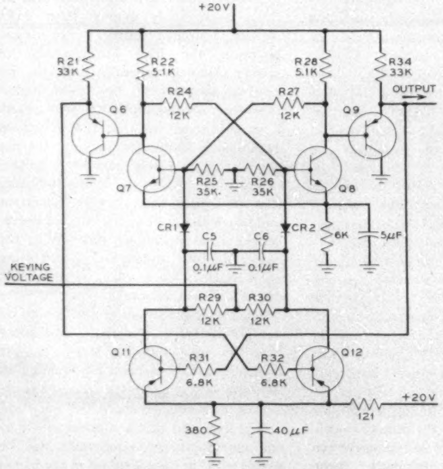

Fig. 5. FM modulator circuit

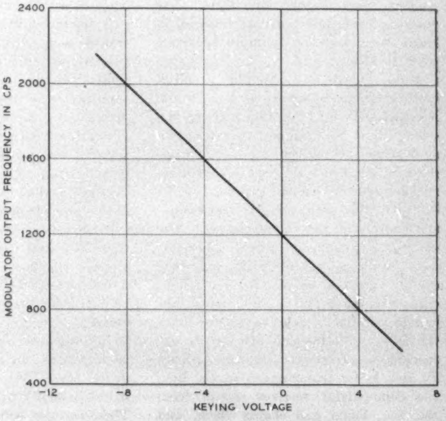

Fig. 6. Output frequency versus keying voltage

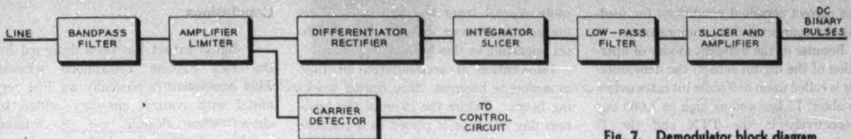

Fig. 7. Demodulator block diagram

is immediately recharged to the ON voltage of *Q11* collector preparatory to the next half-cycle. This voltage rise also back biases diode *CR1*, thus isolating the trigger network from transistor *Q7*. The latter previously has been turned off and the resultant rise in collector voltage has been coupled through *Q6* to turn off *Q12*. This results in unclamping *C6*, which will start to discharge toward the keying voltage for the next half-cycle. The circuit is symmetrical, so that the same action occurs during the second part of the cycle. A very linear frequency versus voltage characteristic is obtained from this stage; see Fig. 6.

The output of the modulator stage is sent through a harmonic suppression filter to eliminate all harmonics from the square wave generated, so that the line signal is essentially sinusoidal. A line amplifier is provided to couple this signal to the telephone line. The amplifier is capable of delivering a maximum output to the line of about +10 db above one milliwatt into 600 ohms. The normal output level will be about 0 db above one milliwatt at this point.

Notice that the block diagram of the modulator shows a block called carrier control; see Fig. 4. This is necessary to permit transmission of carrier only at appropriate times. Since the digital subset is connected to the telephone plant over a 2-wire telephone line, and since the same frequencies are used in both directions the carrier must only be turned on at the transmitting station. The carrier control senses mark-space transitions from the data equipment and turns the carrier on only when data is being transmitted. It is arranged so that when transmission is via teletypewriter keyboard in the TTX mode of operation, carrier is immediately transmitted when an attendant depresses a character on the keyboard. Carrier will remain on for about 300 milliseconds after the last mark-space transition so that during normal-speed typing, carrier is on continuously. On the other hand, if back-and-forth operation is desired, the other end of the circuit can seize control of the channel after this time interval has expired. The carrier control is also arranged to turn on carrier in response to an instruction from a connected data machine for the case where no rapid turnaround of the circuit is contemplated. The carrier control turns off carrier by causing a transistor switch to conduct, connecting collector and emitter of *Q8*; see Fig. 5.

Digital Subset Demodulator

A block diagram of the demodulator is shown in Fig. 7. The line signal is fed through a band-pass filter to an amplifier limiter. The limiter is designed to provide a standardized square-wave output of constant amplitude over about a 40-db range of input levels. It makes use of six transistors in two feedback amplifier combinations. The circuit is arranged so that no feedback is effective at lowest input levels. Diodes in the feedback path open at high levels, resulting in large feedback ratios. Additional shunt diode limiting is used at the highest levels. Fig. 8 shows typical waveforms at various places in the demodulator. The FM input to the digital subset is shown in (A) and the limiter output is shown on (B). Following the limiter is a differentiating circuit whose output consists of positive and negative pulses at the zero crossings of the input wave. These are shown at (C) in Fig. 8. These pulses are put through an inverter which turns over the positive going pulses; its output is a series of negative pulses at twice the carrier frequency; Fig. 8(D). These pulses trigger a transistor blocking oscillator which puts out negative pulses of about 15-microsecond width, each of which corresponds to a zero crossing of the original line signal. When the input is marking (lower frequency) these pulses are spaced farther apart than when the input is spacing (higher frequency). Following the blocking oscillator is an integrating stage. This stage charges a capacitor between pulses. If pulses are occurring at a high rate (spacing line signal) the capacitor in this stage does not have time to charge to its full potential before being reset by the next pulse. If the pulses occur at a lower rate this charging process will proceed to a higher voltage before being terminated. The next stage is a slicer which discriminates between these two charge levels. The waveform after slicing is shown in Fig. 8(E). The slicer output is averaged in a low-pass filter and it passes to a second slicer which produces sharp square waves at the desired bit rate as shown in (F). An output stage is used to provide

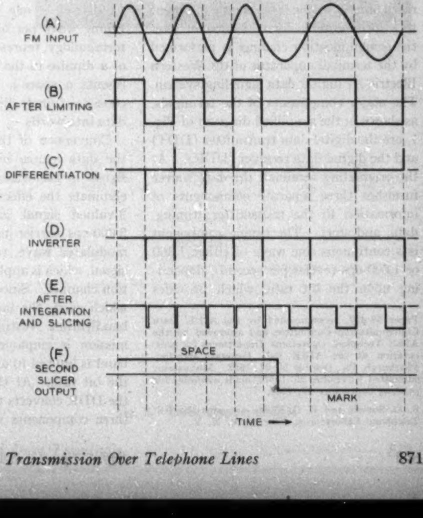

Fig. 8. Digital subset waveforms

the correct terminal conditions for feeding the connected data equipment.

Because of the different modes of operation of the digital subset, the demodulator is called upon to handle bit rates as low as about 75 bps and as high as 1,000 bps respectively in the TTX and the D modes of operation. Optimum low-pass filters differ for these different bit rates so that different filters are used under control of the mode selection relays in the control circuit.

A carrier detector block is shown in Fig. 7 in the demodulator. For control purposes this circuit gives an indication whenever carrier (either marking or spacing) is received by the demodulator. This might also be used to give an end of message indication to an attendant.

Unattended Operation

An attractive possibility in Dataphone service is remote delivery and pickup of data at a station which is unattended. The digital subset is arranged to allow operation of this sort in conjunction with *28ASR* teletypewriters equipped with remote control stunt box features. Tests are now under way with the digital subset operating in this fashion.

Information is accumulated on tape at a remote business office during working hours. Before the close of the business day the tape is placed in a suitable tape-transmitting device. During the evening hours a central record location reaches the unattended station by telephone in the usual way. The digital subset is arranged to answer the call automatically and to set itself into the TTX mode of operation. In this mode of operation the *28ASR* at the remote station is able to respond to special codes typed at the controlling point. For example, the attended station may type a code which tells the remote station to transmit the previously prepared message via some high-speed data machine and the digital subset. Receipt of this code will cause the digital subset to switch to the proper mode for this transmission and to start the tape machine sending. After the transmission the controlling point can initiate another action if required or can type a special code to cause disconnect.

Conclusions

A digital subset has been designed for the Bell System Dataphone service. This equipment is basically an FM terminal with control circuitry added to allow rather flexible use. A limited number of these terminals have been manufactured for trials in various fields of data transmission. It seems certain that the demands on the communication industry for better and more flexible means for transmission of data will multiply several times in coming years. The digital subset described in this paper is merely a beginning in this field of service.

IN THE SAGE (semiautomatic ground environment) System,[1,2] the function of converting the data in the form generated or used by the processing equipment to a form suitable for transmission over the communication channel is performed by the terminal apparatus of the Western Electric *A1* digital data signaling system. The major components of the terminals, as shown in the simplified diagram of Fig. 1, are the digital data transmitter (DDT) and the digital data receiver (DDR). At the originating terminal, the data source furnishes three separate components of information to the transmitter: timing, data, and start. The timing component is a continuous sine wave of either 1,300 or 1,600 cps (cycles per second), depending upon the bit rate, which provides means for synchronizing the system. Message information, contained in the data component, is in the form of dipulses. (A dipulse is one complete cycle of the timing wave per bit, which, in telegraph terminology, represents a mark. Absence of a dipulse in the data component represents a space.) The start component consists of single dipulses which group the data into words.

Conversion of the three outputs from the data source into a single, 3-valued signal is performed by the DDT. To eliminate the effect of carrier shift, this 3-valued signal is modulated with a 2,000-cps carrier to form an amplitude-modulated wave, referred to as the line signal, which is applied to the communication channel. Since some of the channels which carry the line signal have narrow bandwidths, vestigial side-band transmission is employed; the usable sideband is limited to approximately one half the bit rate. At the receiving terminal, the DDR converts the line signal into the three components which are faithful reproductions of the original information from the data source. These components are then fed into the data-using equipment.

Digital Data Transmitter

The DDT may be divided into four parts: timing, data, start and modulator circuits. Three of these parts act upon the information signals from the data source to form a single 3-valued signal. The fourth part, the modulator circuit, combines this signal with a carrier to produce the amplitude-modulated line signal, which is transmitted over the communication channel. These four sections are shown in block diagram form in Fig. 2. For the purpose of illustration, a segment of a word is shown which has its start pulse at t_0 and four marks or data bits in positions t_3, t_7, t_8, and t_9. In the SAGE System, the word length may vary up to 326 bits.

The three inputs to the DDT have the same amplitude, phase, and frequency. The timing component is applied through a narrow-band filter which reduces noise or any other distortion which may occur during transmission of the signal from the data source. After filtering, the signal passes through an adjustable phase shift circuit and is applied to a slicer where the

sine wave is converted into rectangular pulses. These pulses, in turn, are differentiated to form positive and negative spikes which are applied to a normally cut-off amplifier so that only the positive spikes cause it to conduct. The output of this amplifier consists of negative spikes, which are employed in the sampling gates of the data and start circuits. The adjustable phase shifter is used to center the sampling spikes.

In the data section, the data component of the input is sliced to convert the dipulses into rectangular pulse form. Two outputs are derived from the slicer, one when a data pulse is present, and the other for the no-data condition. These outputs are applied to the sampling gate and they steer the timing spikes to the inputs of the data flip-flop. The flip-flop always remains in the last state into which it was driven. Since the circuit is driven both on and off, the output must necessarily be an integral number of periods of the timing wave. The flip-flop responds to the timing spikes to produce negative-going rectangular pulses when data is present in the input signal.

Operation of the start circuit is similar to that of the data circuit. Start dipulses are sliced and the output is applied to a gate where it is combined with timing spikes to drive the start flip-flop. However, the positive output pulse of the flip-flop is used to indicate the presence of a start dipulse.

A summing network combines the outputs of the data and start circuits to produce a 3-valued signal. This composite signal is applied to the modulator through a low-pass filter which removes the frequency components above 1,000 cycles. In the modulator the composite signal is combined with a 2,000-cps carrier to form the line signal. The modulator output passes through a negative feedback amplifier and is then pre-equalized to compensate for delay and amplitude distor-

tion in the entire transmission system. Extraneous modulation products are removed by filtering before the signal is applied to the communication channel.

Digital Data Receiver

As mentioned previously, the function of the digital data receiver is to reproduce the timing, data, and start components of the transmitted information from the line signal. To perform this function, the DDR must:

1. Detect the presence or absence of data and start pulses in the line signal.
2. Generate a timing wave which is synchronous with the original timing and which is properly phased, relative to the data signal.
3. Produce as outputs, data, and start dipulses which are faithful reproductions of the original signals from the data source and also a timing wave with the proper phasing.

The major sections of the DDR are shown in block diagram form as part of Fig. 1. Briefly, the receiver operates as follows: At the receiving terminal, the line signal is applied to a band-pass filter which provides the vestigial side-band shaping and also removes the out-of-band noise accumulated during transmission. The filtered signal is demodulated to recover the modulation envelope which consists of a wave containing positive and negative peaks representing the start and data pulses, respectively. These pulses are separated in proper sequence by the decoder section. Since the time duration and phasing of these pulses may be variable because of line noise and other irregularities, the start and data pulses are regenerated in the decoder. The regenerated pulses are then applied to the modulator section where dipulses are produced.

Start pulses from the decoder section are also used to control the frequency and phase of the timing generator. The output of the timing generator consists of timing spikes, which are used for pulse regeneration in the decoder section, and a sine wave which is applied to the modulator section. The modulator uses the start and data pulses from the decoder to gate the timing wave. In this manner, portions of the timing wave are transmitted as dipulses to the data and start outputs. In addition, the timing wave is continuously transmitted through another channel to the timing output.

The following paragraphs describe the operation of the various sections of the DDR in greater detail.

Demodulator

Fig. 3 shows the demodulator section in block diagram form along with the waveforms at various points in the circuit. In the demodulator, the filtered line signal is amplified, full-wave rectified, and filtered to recover the original 3-level signal. Positive peaks of the recovered envelope represent start pulses, while the negative peaks represent the data pulses. Since the proper operation of the remainder of the DDR circuit depends upon the signal being held to a close tolerance, an AGC (automatic gain control) system is employed. The peak of the start pulse is compared with a direct-voltage reference of approximately 45 volts. The difference is amplified, rectified, and filtered to provide the AGC voltage. This voltage is modified by a diode-resistor network to match the voltage-versus-gain characteristic of the amplifier.

Fig. 5. DDR modulator

The peak of the start pulse, rather than the average carrier, is used to control the amplifier gain because the value of the average carrier is a function of word composition and thus may be continually changing. The value of the start peak, however, is fixed, and therefore it becomes a good reference point. Nevertheless, a considerable burden is placed on the AGC circuit since there may be more than 300 data bits between start pulses.

DECODER

Conversion of the 3-level output from the demodulator into data and start components takes place in the decoder, shown in Fig. 4. The modulator output is connected to a pair of slicers, one for recovering start pulses and the other for recovering the data pulses. These slicers are 2-stage differential amplifiers having an accurate, fixed bias corresponding to the mid-point of the desired slice. Use of two gain stages insures that the second stage will overload rapidly, resulting in a maximum slice thickness of about one volt. The slicer outputs are rectangular pulses. These pulses, however, are too greatly distorted to control the dipulse modulator directly. Therefore, in a manner similar to that described for the transmitter, the slicer outputs are used to control gates, which steer accurate timing spikes from the timing generator to control flip-flop circuits.

Both the start and data flip-flops are arranged to produce a positive output to indicate the presence of a pulse in the 3-level signal or a negative output when there is no pulse. A no-data gate combines the two negative outputs to provide an output to the modulator when there is neither a start nor a data pulse. The reason for this output will be explained in the description of the modulator section.

MODULATOR

The modulator section, shown in Fig. 5, is composed of balanced, gate-type modulators. Positive pulses from the decoder section start and data flip-flop circuits actuate the modulators to permit application of the sinusodial wave from the timing generator to the start and data outputs. This timing wave is distributed to the timing output as well as to the modulators. All three outputs must be held to the same level, within a fraction of a decibel. Therefore, a pad is added in the timing output to compensate for the loss in the start and data modulators. Since the input impedance of the modulator is very high when there is no gate pulse and is 600 ohms when a gate pulse is present, the termination presented to the distributing pad by these two modulators will vary with the composition of the 3-level signal. Such a variation could result in a modulation of the timing output unless, of course, the timing amplifier supplying the signal has a very low output impedance. The alternative to a low-impedance amplifier is to keep the termination of the distribution pad from varying. This has been accomplished

by providing a dummy modulator which is controlled by the output of the no-data gate. The dummy modulator provides a 600-ohm termination when there are neither start nor data signals. As a result of this method of operation, the distribution pad is properly terminated at all times and the timing output is independent of word composition.

TIMING GENERATOR

The timing generator section may be divided into two main circuits a phase error detector and a variable oscillator. Block diagrams of these circuits are given in Fig. 6.

To provide a satisfactory error rate in the transmission of data over a noisy communication channel, the sampling spikes used in the regeneration of data must have a frequency exactly equal to the bit rate of the data source. In addition, the spikes must be accurately phased with respect to the line signal. The latter problem will be dealt with first. Because of the narrow transmission band provided by some of the communication channels, timing recovered from the data transitions cannot be employed to establish the phase, since word composition could cause the phase to vary by as much as ±90 degrees. The method used to establish the proper phase is based upon monitoring the sliced start pulse and insuring that the sampling spike is located at the mid-point of the pulse. To obtain the desired accuracy of the phase obtained in this manner, the shape of the pulse on the line signal must be independent of word composition. This is attained by restricting the word make-up so that data pulses will never occur within two bit positions of either side of the start signal (i.e., marks cannot occur in bit positions t_1 and t_2 or the two bit positions preceding t_0).

A phase error signal is obtained in the following manner. Outputs of the start slicer and the start flip-flop of the decoder section are compared, and a positive pulse is generated having a length equal to the time from the leading edge of the sliced start pulse to the leading edge of the start flip-flop pulses. The latter point corresponds to the occurrence of the sampling spike. Similarly, a negative pulse may be derived which has a duration equal to the time from the occurrence of the sampling spike to the trailing edge of the sliced start pulse. These two pulses are integrated to produce direct voltages of opposite sign which are proportional to the pulse durations. By adding the voltages in a summing network, the resulting algebraic sum provides an output signal which supplies both the magnitude and direction of the phase error. This signal is then used to control the frequency and phase of the oscillator section.

Requirements for the variable oscillator are quite severe. It must be easily varied to correct for both its own variations and the variations in the source timing. To permit pulling in and locking on 326-bit words, the variation in the frequency of the oscillator, including the controlled variation, must not exceed ±0.1%. While a tuning fork oscillator will meet the accuracy requirement, the frequency of such a circuit is not easily varied. An L/C (inductance-capacitance) oscillator can be varied easily, but it will not meet the ±0.1% requirement. To solve this problem, a circuit was devised which uses both types of oscillator. A tuning fork oscillator provides a frequency of 1,000 cps when the bit rate is 1,300 bits per second or 1,300 when the bit rate is 1,600 bits per second. A variable L/C oscillator provides a 300-cps frequency. The two frequencies are combined in a double balanced modulator and the desired component is recovered by filtering. As a result of this method of operation, the accuracy of the 300-cps oscillator must be held to ±0.4%.

The L/C tank of the variable oscillator is tuned to a nominal frequency of 300 cps, and the amplifier section of this oscillator is arranged so that its phase shift of 300 cps may be varied as a function of the phase error voltage. Since the net phase shift in the loop must be 360 degrees, the frequency of oscillation changes until this requirement is met.

Amplitude stability of the timing wave is obtained by comparing the timing wave

GENERAL PERFORMANCE OF THE DDR

The *A1* digital data signaling system has been designed to work over standard telephone communication channels. James discusses these channels in detail.[3] However, to provide some details of the receiver performance, a brief discussion is given here of several of the transmission considerations connected with the use of telephone circuits.

Input signal level: The level of the line signal at the input to the DDR may vary as a result of differences in the net loss in connecting facilities, seasonal changes, etc. The signal level within the DDR, however, must be maintained within a close tolerance by the AGC circuit. As mentioned previously, the peak of the start pulse is used to control the gain of the receiver amplifier. Since the time between start pulses varies with word length, and since the gain control voltage is stored in a capacitor, the range of input levels which may be tolerated is a function of the word length. As a result, there exists a "word length-input product" which is somewhat analogous to the gain-bandwidth product of an amplifier. When the word length is 64 bits, for example, a range of input levels of 35 db (decibels) will cause a variation of only ±0.1 db in the demodulated signal. For a word length of 326 bits, the input level range which causes the same demodulated signal variation is 20 db.

Sudden level changes: A sudden level change in the input may occur when an automatic switch takes place in the communication channel or when a carrier system employing a pilot wire regulator produces a step change in gain. The amount of sudden level change which will not cause errors in the DDR is a function of both the input level and the word length, and varies from 0.75 to 1.75 db. The maximum theoretical sudden change which can be tolerated for this type of line signal is 1.8 db.

Induced noise: Laboratory tests and limited field experience have shown that the DDR functions satisfactorily in the presence of thermal noise of about 53 decibels adjusted measured at a point where the level of the start peak of the line signal is zero decibels referred to one milliwatt. This is equivalent to a peak signal to rms noise ratio of 37 db. Impulse noise peaks 18 db below the start peaks do not cause the DDR to exceed its allowable error rate. These values are reasonably close to the theoretical maximum allowable values.

Digital Data Terminals

Actually, the DDT and DDR constitute only a part of the digital data terminals. Complete transmitting and receiving terminal arrangements for a dual facility, i.e., a circuit which, for reliability reasons, has two separate communication channels, are shown in Fig. 7. In this illustration, the data source is supplying information to a single using equipment. The three information components from the source are applied to the two transmitters through input circuits which contain splitting pads for dividing the signals and jacks for testing and patching. Line signals from the DDTs pass through jacks in the output circuit before being applied to the communication channels. Either channel may be used as the working circuit with the other as the stand-by.

At the receiving terminal, the line signal is split between the DDR and a monitoring circuit called the trouble detector. One of the functions of the

Fig. 9. Test setup

T
S
DDT
DDR
D
T
MATCHING AND ERROR COUNTER

trouble detector is to determine when the communication channel becomes excessively noisy, a condition which could cause errors in the data. If, for example, the working channel becomes too noisy, the trouble detector actuates the transfer and control circuit which, in turn, switches the data-using equipment to the other channel. This switch will still be maintained when the trouble condition is cleared. The trouble detector also monitors the start output of the DDR. Loss of this output, which indicates trouble either in the communication channel or in the receiver, also results in the operation of the transfer and control circuit. When operating under control of the trouble detector, the transfer and control circuit will not switch to a circuit that is already in trouble.

The transfer and control circuit may also be operated manually at the using equipment. Associated with the circuit are lamps to indicate the status of the receivers (good or not good for service) and an audible alarm which signals the occurrence of a trouble condition.

Equipment arrangement for a digital data terminal is shown in Fig. 8(A) and (B). Since information is sent in both directions, this terminal has both transmitters and receivers. Fig. 8(A) shows a bay with four DDTs and six DDRs. The bay in (B) contains the DDT and DDR assigned for test purposes, spare transmitters and receivers, and four transfer and control circuits with the associated trouble detectors.

System Testing

The measure of effectiveness of any communications system is the ability of that system to transfer intelligence while preserving its form within prescribed limits. To maintain this effectiveness, some method of testing is required. The method used and the means by which it is performed is peculiar to the equipment involved. Fig. 9 shows the testing method and special equipment used in the test of the digital data terminals.

One major difficulty encountered in testing digital equipment arises from the nature of the digital data signal. To test any piece of digital data equipment, a known signal source is required. Digital data, in the form of start and data dipulses, together with the extremely accurate timing wave must be produced locally before any other testing may be considered. The local generator must simulate all conditions of the actual signals and must be able to control word length, amplitude and phase. These functions are provided by a special test circuit called the word generator.

When the word generator is employed as a test signal source, feeding a DDT, a local oscillator generates the timing wave, and segments of this wave, forming dipulses, are gated under control of a counting circuit to the start and data outputs of the word generator. The word generator provides means for controlling the word length as well as the location of the data pulses, and it continually repeats the fixed word pattern which is applied to the DDT. The transmitter then sends out this fixed pattern as the line signal.

At the receiving end of the circuit, a means for accurately checking the data, pulse by pulse, is required. The test equipment must be able to match pulses from two synchronized local sources of data and to record the existance of mis-

matches. These functions are performed by a second word generator (designated as word generator 2 in Fig. 9), and a matching and error counter.

Word generator 2 is set to have the same data pattern as word generator 1. Instead of generating its own timing, however, word generator 2 depends on the timing frequency generated by the DDR. The timing is fed through the matching and error circuit, which insures that the two word generators and the matching and error counter work on the same time base. Word generator 2 uses the start pulse from the DDR to synchronize its output with the DDR output. The bay arrangement for the test equipment is shown in Fig. 10.

Electrical Features of Indian Point Nuclear Electric Generating Station

T. D. REIMERS
FELLOW AIEE

THE Consolidated Edison Company of New York is building a nuclear electric generating station on the Hudson River at Indian Point about 24 miles north of New York City. Fig. 1 is an aerial perspective sketch indicating the general arrangement of the completed plant.

The reactor is of the pressurized-water type using a mixture of highly enriched uranium oxide and thorium oxide as a fuel. It will operate at 1,500 psig (pounds per square inch gage) and at an average coolant temperature of 501 F (degrees Fahrenheit). The primary coolant system consists of four parallel loops which circulate demineralized light water between the reactor vessel and the steam generators. Two canned motor pumps circulate the water in each loop. The steam generators produce steam at 449 F and 405 psig. This steam will pass an oil-fired superheater to raise the temperature to 1,000 F and deliver 2,200,000 pounds of steam per hour to the turbine at this temperature and 355 psig.

The turbogenerator is a tandem-compound 1,800-rpm condensing unit with an estimated gross operating capacity of 275,000 kw.

The reactor, steam generators, and primary circulating pumps are housed in a pressuretight 160-foot-diameter steel sphere. To protect the public and personnel who will operate this unit and adjacent units in case of an accident in the sphere, an external radiation shield of concrete 3 to 6 feet thick surrounds the steel sphere.

Fig. 2 is an elevation showing the location of the main plant components.

Electrical Features Differing from Conventional Plant

It has been the aim of Consolidated Edison to make the design of the electrical features of this plant conform as closely as possible to that of their conventional plants. In most respects these features have been maintained.

However, particularly for the nuclear portion of the plant, there are certain requirements at the present state of reactor development which necessitate modification of conventional electrical designs. This paper deals particularly with these differences and the design modifications which result.

Reactor safety requirement suggests changes in the auxiliary power supply, control sources, controls, and instrumentation. To ensure safe operation, considerable reactor instrumentation is duplicated and triplicated. Very little instrument duplication is provided in the conventional plant.

Radioactivity, humidity, and temperature in the sphere present an insulation problem.

The large capacity of the generator with respect to a high-impedance tie through an adjacent company's system presents a stability and voltage-regulation problem under certain operating conditions.

Auxiliary Power Supply

For conventional unitized generating units Consolidated Edison has been providing one start-up source from an adjacent substation for the unit auxiliary power bus and has transferred this bus to the generator as a supply source as soon as this unit was synchronized to the system. In the event of the unit being automatically cleared from the system by operation of protective relays or boiler-turbine-generator sequence trips, the supply to the auxiliary bus becomes deenergized. Under this condition some lighting and a few small essential auxiliaries are automatically transferred to the start-up source.

In the reactor plant it is desirable to

maintain, at all times, supply to as much as possible of the reactor's electrically driven auxiliaries. To prevent possible reactor core damage in a "scram" operation, it is necessary to maintain service to at least one primary circulating pump, one seal make-up pump, one boiler-feed pump, electrical control and instrumentation sources, other small essential equipment, and essential lighting.

To provide this reliability the 13-kv auxiliary power bus has been designed in four sections. One bus is supplied from the generator terminals, two busses are each supplied by a feeder from different bus sections of an adjacent distribution substation, and the fourth bus is supplied through a step-down transformer from a 138-kv tie feeder to the neighboring Orange and Rockland Utilities, Inc., system.

Fig. 3 is a one-line diagram of the main connections and the auxiliary system.

Normally, the four 13-kv auxiliary bus sections are operated with the bus tie circuit breakers open. When the normal supply to a bus section becomes de-energized, that section may be tied manually to another section. No automatic transfer is provided for the 13-kv busses.

Each 13-kv light and power bus section has one feeder supplying load in the nuclear portion of the plant and one feeder supplying load in the conventional part of the plant.

These 13-kv feeders supply 937-, 1,250-, 2,000-, and 2,500-kva sealed dry-type transformers in load center substations located close to the large auxiliary motors or load areas. Each 1,600-hp (horsepower) coolant pump motor is supplied from its own 2,300-volt grounded-Y load center. All other load centers supply 440 volts grounded Y except for two 125/216-volt grounded-Y units supplying lighting and small auxiliaries.

Automatic throwover from its normal load center source to a source fed from a different 13-kv bus section is provided for the following equipment:

One fresh-water cooling pump and one river-water cooling pump for the nuclear plant cooling requirements.
Generator-exciter motor-generator set.
Valve motors.
Essential turbine shutdown auxiliaries.
One battery charger of each d-c control voltage system.
Main turbine auxiliary oil pump.
Fire pumps.

Remote manual transfer is provided for the following:

One spent-fuel cooling pump.
One process transfer pump.
One decay-heat cooling pump.
One seal and make-up pump.
One pressurizer heater group.
One containment cooling fan.
One control rod hydraulic pump motor.

Control and Instrumentation Supply

In Consolidated Edison's conventional plants control power is supplied at 125 volts d-c from two busses each having a battery and a rectifier or a motor-generator set. Control centers are fed from both busses through interlocked automatic throwover switches.

The 125-volt 60-cycle circuits for instrumentation are supplied from a bus fed from two 125/216-volt load centers through an interlocked automatic throwover switch.

In the nuclear plant much of the reactor instrumentation requires an exceptionally reliable 125-volt a-c supply for electronic circuits used in monitoring reactor operation. Severe voltage dips or an interruption of even a cycle to this a-c instrumentation supply would cause "scramming" of the reactor.

To provide this reliable supply, 3-unit motor-generator sets have been specified each having a normal drive motor supplied from one of the 440-volt 3-phase 60-cycle load centers, a d-c generator connected to a 125-volt d-c battery bus, which acts as a motor when the normal a-c drive supply becomes de-energized, and a 125/216-volt 3-phase 60-cycle generator.

The connections of these sets are shown in Fig. 4. Each of two of the sets normally supplies separate 125-volt d-c control and 125/216-volt 60-cycle instrument busses. The third set which is supplied from an essential 440-volt bus can be connected to either of the d-c control and a-c instrument busses through remote-operated selector switches.

Normally, these busses will be operated as shown in the figure. The spare motor-generator set may be connected to either one of the d-c control busses *DC-1* or *DC-2* and the instrument supply busses *60-1* or *60-2*. The respective busses would be tied only in the extreme emergency when the spare set is the only one available.

Important 125-volt d-c control centers will have a supply from each of the two control busses connected to it through an interlocked automatic throwover. The momentary interruption occurring during this transfer does not affect the operation of any equipment connected to this system since no normally energized equipment is supplied from this system.

Half of the nuclear instrument circuits requiring a reliable supply will be fed from each of the two 125-volt 60-cycle instrument busses. In the event that the normal a-c motor driving the associated a-c generator is de-energized, the set will continue to be driven from the battery of the 125-volt d-c bus by means of the d-c generator now operating as a motor. In such instances, the battery can usually be relieved by connecting the spare motor-generator set to the affected busses. In the extreme condition of losing the 440-volt supply to all the motor-generator sets, the reactor will have been scrammed by the safety protective system, and only a few instruments will have to be kept in service to monitor the conditions in the reactor core. By manually switching off all other circuits, the essential monitoring equipment can be operated by one of the a-c generators driven from the battery for at least 24 hours.

The reactor rod control system requires a 400-cycle power supply for magnetic amplifiers. This supply must also be exceptionally reliable because its loss for only 5 milliseconds will cause the reactor to scram. This supply is obtained from a 3-unit motor-generator set with a flywheel consisting of two 440-volt 60-cycle motors, each fed from a different auxiliary power source, driving a 400-cycle 120-volt generator. The loss of either normal 60-cycle supply source can be tolerated without affecting the 400-cycle power supply. A normally shutdown spare set is installed for this system.

A 48-volt d-c system is used for alarm circuits and for remote operation of switchgear.

Nuclear Instrumentation

The nuclear instrumentation differs from conventional boiler instrumentation in several ways:

1. The primary variable is neutron density in the reactor, as compared with fuel-firing rate in a conventional boiler.
2. The range of the variable is from $10^{-9}\%$ to 150% of power level, as compared with 1% to 100% for a boiler furnace.
3. The nature of the variable displayed and recorded is log power level and linear power as compared with temperature, steam flow, etc.

Another important distinction is that the nuclear instrumentation provides the information required for the control and the safety system, while on conventional furnaces the control and the safety systems are entirely separate.

Fig. 4. D-C control: 60-cycle instrumentation and 400-cycle control systems

The proposed nuclear instrumentation, shown in Fig. 5, will provide ten separate channels of information. These ten channels divide into two groups, distinguished by their operating range. The first four channels are strictly start-up ranges covering the power level from start-up neutron source ($10^{-9}\%$) to 0.1% of full load.

The other six channels overlap the upper end of the start-up range of power level and extend to 150% of full power. These are divided into two groups of which three channels provide log-level and period* information from $10^{-3}\%$ to 100%, while the other three channels display linear power level from 0.1% to 150%.

There is intentional duplication and 2-decade overlapping because of the extreme importance of this instrumentation to both the operators and the safety system. Thus, channel *2* duplicates channel *1*, both operating from neutron counters and providing indication of log count rate and period, which operate indicating instruments and recorders and, through an "auctioneering" device for log count rate and period, provide a signal from the higher of the two channels for optional use in the safety system. The auctioneer-

ing device is an electronic device which chooses the higher (or lower) of two signals and passes on the chosen signal.

Similarly, channel *4* duplicates channel *3*, both providing log-count-rate and period information in the range of 10^{-8}% to 0.1% of full power. Auctioneering is used as in channels *1* and *2* and signals of count rate and period are available for optional use in the safety system. These channels also supply indicating instruments and recorders.

Channels *5* through *7* are triplicates. They measure log power level and period in the range from 10^{-3}% to 100%, supplying indicating instruments and recorders, and providing a signl to the safety system from each channel. These safety system signals are "fail-safe" in that zero signal denotes a hazardous condition. If one of the three channels delivers a zero signal, an alarm indication is initiated. A second zero signal from these three channels causes the safety system to scram the reactor.

Channels *8* through *10* are also triplicates. They provide indicated and recorder information of linear power level in 0.1% to 150% of full load. In addition, they provide safety system signals with the same features as channels *5* through *7*. Furthermore, these channels furnish signals to the automatic control system and the flux-flow computer. This device computes the ratio of the reactor neutron flux level to coolant flow and functions as a component of the reactor control system.

All of the reactor instrumentation involves neutron counters of various types, electronic amplifiers of the tube and magnetic designs with power supplies, auctioneering, and averaging circuitry, etc., which are to be installed in enclosed, ventilated cubicles in groups such that a fire in any one cubicle will not affect more than one channel. Temperature of the atmosphere in each cubicle will be monitored.

Since 1953 Consolidated Edison has been using an integrated automatic trip protection system for turbine generators and boilers, which was described 5 years ago in an AIEE paper.[1] This protection has proved very satisfactory in detecting undesirable conditions not immediately recognizable by the operator and in reducing the extent of damage. The system has proved very reliable and false tripping has been at a minimum.[2]

In the instance of the nuclear plant, essentially the same automatic protection will be provided for the turbine and superheater as would be provided normally for the turbine and boiler. Fig. 5 shows the additional protection for the nuclear reactor and its interconnection with the superheater, turbine, and generator protection.

Fig. 6 shows the over-all automatic protection of reactor, superheater, and turbine generator.

Insulation Problems in Reactor Sphere

Electrical insulating materials in the nuclear sphere will be subjected to conditions considerably more severe than in conventional power plants.

Ambient temperatures of 45 to 65 C (degrees centigrade) are expected to exist normally in the nuclear sphere, as compared with 40 to 50 C in the conventional plant. Humidity conditions in the sphere will be more severe and may at times approach 100% relative humidity.

Electric equipment in the sphere will be normally subjected to radiation of 50 to 150 roentgens per hour, a problem which does not exist at all in conventional plants.

All power, control, and instrumentation cables entering the sphere must be so installed as to prevent leakage at operating pressures up to 25 psig which may occur during an accident in the reactor.

To minimize difficulties associated with electrical insulating materials under these more severe conditions, every effort has been made to place electric equipment outside the phere. This will also aid in maintenance since the radiation level prohibits employees from entering the sphere under operating conditions. All major contactors, switches, and similar equipment are located outside both the sphere and concrete radiation shield. Limit switches and terminal boards which have to be located in the sphere are of glass-base materials with silicone impregnants. Such devices generally will be in watertight housings. There are some 75 electric motors in the sphere ranging from fractional to 1,600 hp.

All motors in the sphere will be totally enclosed and will have class *H* insulation for maximum resistance to temperature and radiation effects. The primary circulating pump motors are of the canned type.

Motor circuits will be glass-tape silicone-rubber-impregnated lead-covered cable. The cable will be wiped to glands at the gasketed motor terminal box. Cables of 2,300 volts such as used for the 1,600-hp coolant pump motors and other large 440-volt cables will be terminated at the sphere wall in solder seal potheads whose metal body is welded to the sphere wall with the porcelain section outside the sphere and with the lead sheath of the cable wiped to the pothead gland inside the sphere.

Low-voltage small power and control cables will be lead covered and will be brought into the sphere through wiping glands as shown in Fig. 7. The several insulated conductors will be sealed in this sleeve with a suitable filling compound which hardens, fills in the spaces, and seals to both the individual conductor insulation and to the sleeve. Investigations and tests are now in progress to select the most suitable wire insulation material and filling compounds for this purpose and to withstand the radiation and temperature effects.

Both the potheads and the smaller wiping sleeves which penetrate the sphere must hold the 25-psig pressure which may be obtained in the sphere in a reactor accident. They will be designed for twice this pressure.

Outside the sphere the cable insulation for 2,300- and 440-volt power cables and for control cables will be ozone-resisting compound rubber as used in present stations.

Connection of Nuclear Generator to System

Fig. 8 shows the connections of the Indian Point nuclear electric generating plant to the Consolidated Edison and neighboring systems. The unit feeds at 138 kv into the new Buchanan substation located about three quarters of a mile from the generator. This substation has two 138-kv ties to Consolidated Edison's Millwood substation and one 138-kv tie connected to Orange and Rockland Utilities 69-kv system at Lovett generating station through a step-down autotransformer. Note that there is another tie loop from Lovett through the Orange and Rockland–Central Hudson–Niagara Mohawk systems back to Millwood substation.

The connection of this machine at a point on the systems having two large-capacity low-impedance ties on common towers in one direction and a single high-impedance tie through smaller systems in the other direction presents some operating problems should the Buchanan-Millwood lines become opened for any reason.

Either of the Buchanan-Millwood lines alone are adequate for the transmission of the 275-mw (megawatt) capacity of this new nuclear-powered generator to the system. If both of these lines are out of service, only about 75 mw of the total output can be absorbed locally and transmitted satisfactorily through the high-impedance ties of the Orange and Rockland–Central Hudson–Niagara Mohawk systems.

Network analyzer studies indicate that the simultaneous tripout of both Millwood

lines with the nuclear unit carrying loads in excess of 150 mw would create a stability problem in the neighboring Orange and Rockland Utilities system. These studies also indicated that it would be inadvisable to attempt to reclose these lines with the Indian Point generator previously operating near its maximum capability because of the very large resultant current surges.

Further investigation showed that if the Indian Point generator was also tripped on the occurrence of a double Buchanan-Millwood tie outage, under peak load conditions and the outage of even a small Lovett generator, the neighboring system could not support both the Buchanan substation and the Indian Point auxiliary essential load.

The probability of obtaining the combination of the foregoing conditions is remote, but the requirement of a reliable supply to the essential Indian Point auxiliaries has led to the adoption of the following protective scheme:

Under any condition where the Indian Point generator output exceeds 75 mw, an opening of both of the Millwood ties will also scram the reactor and trip the generator and the Orange and Rockland tie breaker at Buchanan. This leaves the essential nuclear auxiliary load connected through a transformer on the feeder side of the Orange and Rockland tie circuit breaker, since this feeder remains alive from the Orange and Rockland system. Millwood tie or ties will automatically reclose if the fault has cleared. If one or both Millwood lines successfully reclose, the Orange and Rockland tie will be permitted also to reclose automatically.

Following this it becomes necessary to restart the reactor, bring the turbine generator up to speed, and resynchronize to the system.

In the event that the Millwood ties lock out on reclosure, the Orange and Rockland tie will not reclose automatically. The restoration of the Buchanan load, the ties and generator, will then be performed manually as load and capacity conditions permit.

Conclusions

1. The electrical features of a nuclear-powered turbine-generator plant are similar in many respects to a conventional plant.

2. To protect the reactor from core damage, a more diversified auxiliary supply is required than for conventional plants.

3. Very reliable sources, unaffected by system disturbances, of 125-volt 60-cycle power for instrumentation and of 125-volt 400-cycle power for the safety and rod control systems are required for the nuclear plant.

4. Over-all reactor-superheater-turbine-generator automatic protection uses the same principles developed for the conventional plant with added information obtained from the reactor.

5. Location of this large unit at an interconnection point having large low-impedance ties to one system and small high-impedance ties through another system presents some unusual protection problems.

A Magnetic-Amplifier Commutating and Pulse-Width Encoding Circuit

W. H. LUCKE
AFFILIATE AIEE

THE DESIRABILITY of replacing the mechanical commutators now used in many telemetering systems by special electric circuits is generally recognized.[1] This desirability is enhanced in rocket, missile, and satellite applications by the demand for high reliability and long life in the face of stringent environmental conditions, e.g., high g forces. The present paper describes such a commutating circuit. This circuit offers several advantages: 1. Mechanical commutation is eliminated. 2. The amplitude variations of the signal sources are encoded as rectangular pulses of variable width but constant height. This feature is particularly advantageous when low signal-to-noise ratios are encountered in the communication link. 3. Considerable power gain is afforded. 4. Solid-state devices, i.e., square-loop cores, transistors, and rectifiers, are used exclusively, hence the circuit can be potted and made very rugged.

General Description

The circuit is designed to accept d-c signals from several sources at a low power level and to present them at a higher power level encoded as constant-amplitude variable-width pulses to the system modulator. This is accomplished by storing information as to the voltage (or resistance) level of a particular source as a flux change in a corresponding core. Subsequently this information is "read-out" of the core as a rectangular pulse of variable width, which is applied directly to the modulator input.

The power source for the circuit is a transistor saturable-core multivibrator, hereafter referred to as the supply. During negative half-cycles of the supply, all signal sources are "sampled" simultaneously, i.e., the flux level in each core is caused to change by an amount proportional to the level of its signal source. On the following positive half-cycle, the output of the supply is applied to each core in turn, driving it to saturation. By Faraday's law the product of this constant voltage and the time it takes the core to saturate is equal to $\Delta\phi$, the flux change caused by the signal source. Prior to saturation the core acts as a transformer; hence the output of a core consists of the transformed supply output voltage existing for the time it takes the core to saturate. Since each

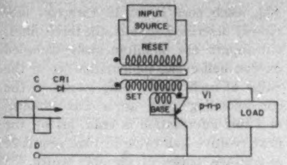

Fig. 1. The basic unit of the sequential set circuit

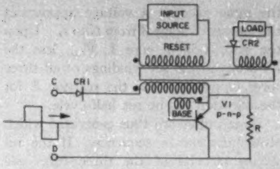

Fig. 2. An alternative configuration of the basic unit

core goes to saturation (i.e., sets), in turn it is clear that the output of the circuit consists of a sequence of variable-width pulses.

It is evident that the key to circuit operation is the means by which cores which are "reset" (i.e., have information stored in them) in parallel are set each in its turn. This is accomplished by a novel arrangement of simple transistorized magnetic-amplifier stages such that, upon the application of the positive half-cycle of the supply, each stage sets in turn, all other stages being quiescent. This basic arrangement (hereafter called the sequential set circuit) forms a flexible unit to which various means of set and reset can be applied, and may be used to form the basis of a variety of circuits for generating a train of pulses.

It should also be mentioned that the circuit is capable of giving a considerable power gain. The power level required of the signal sources is determined by the energy required to reset the core, whereas readout, or set, utilizes energy from a source furnished for that purpose and may be at a high power level.

The Sequential Set Circuit

In the following description of the operation of the sequential set circuit, reference to the sources and application of set and reset voltages will be made in general terms only. This approach has the two-fold object of keeping the description simple and focusing attention on the basic circuit and its possibilities. A description of the means of set and reset will be given later in connection with the discussion of the commutator as a whole.

The basic unit, or stage, of the sequential set circuit is diagrammed in Fig. 1. An alternating square-wave supply voltage is applied to the power input terminals *C* and *D*, which feed the set winding and the p-n-p transistor and load in parallel through the rectifier *CR1*. (The rectifier is necessary to block current in the set windings during reset.) The core is reset from the input source by an amount proportional to the voltage of the source. The source is presumed to present an open circuit to the reset windings during set. The dots are the conventional winding polarity markers.

Now suppose that the core has been reset by an amount $\Delta\phi$ from $+\phi_r$ to some arbitrary ϕ_c. When terminal *C* becomes positive with respect to terminal *D*, magnetizing current will flow through the set winding and the load. However, as soon as flux starts to change in the core, a voltage will be induced in the base drive winding in such a direction as to make the base of the p-n-p transistor negative. With proper design, this base voltage is large enough to hold the p-n-p transistor in saturation, i.e., emitter-to-collector resistance a minimum, for currents equal to the magnetizing plus base-load current which must be passed by the set winding. In the transistor saturated condition, the base-to-emitter voltage is very low—of the order of a few tenths of a volt. Hence, the voltage across the load is a few tenths of a volt; the majority of the current flows through the transistor. This situation holds until the core saturates at a time *t* determined by the relation

$$\int_0^t V_{CD}dt = N_{\text{set}}\int_{\phi_c}^{\phi_s} d\phi = \Delta\phi \qquad (1)$$

where V_{CD} is the supply voltage, N_{set} is the number of turns in the set winding, ϕ is flux, and ϕ_c and ϕ_s are the initial and saturation fluxes.

Upon saturation, the voltage applied to the base of the transistor drops to zero and the emitter-to-collector resistance rises to a large value. The voltage V_{CD} minus the *IR* drop in the set windings is applied to the load until the end of the cycle. During the ensuing negative half-cycle of the supply voltage, reset is accomplished through the reset winding by the signal source, and the cycle is repeated. During reset, the base winding applies a positive voltage to the base of the transistor. This has the effect of further increasing the emitter-to-collector resistance so that the transistor is effectively an open circuit. Current flow in the load is prevented by virtue of the blocking of the rectifier by V_{CD}, which is now negative and must, at all times, be equal to or greater than the voltage induced in the set winding by the resetting voltage, V_{reset}. A silicon-junction diode gives an added margin of safety because of its higher conduction threshold

Since

$$\Delta\phi = \frac{1}{N_{\text{reset}}}\int_0^{T/2} V_{\text{reset}}dt,$$

where N_{reset} is the number of turns of the reset winding and $T/2$ is the half-period of the supply voltage. The greater V_{reset}, the greater $\Delta\phi$. By equation 1 the greater $\Delta\phi$, the greater *t*, and the later in the set half-cycle saturation occurs. Hence output bears a complementary relation to input.

An alternative configuration, in which output bears a direct relation to input, is diagrammed in Fig. 2, where the reset and set circuits are unchanged, but the load has been connected across a winding provided for that purpose. The rectifier in the load winding has been added to block current flow in the load during reset. A ballast resistor *R* is substituted for the original load.

Again assume that the core has been reset by an amount $\Delta\phi$. Upon the application of a positive V_{CD} and the ensuing flux change in the core, the transistor switch is closed. However,

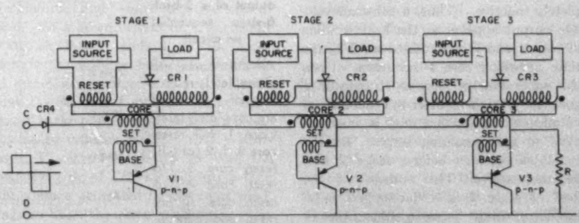

Fig. 3. Simplified version of a 3-stage sequential set circuit

here the base drive must be great enough to hold the transistor in saturation for magnetizing plus transformed load current. In this case, the transformed voltage V_{CD} is applied to the load for the time t for saturation to occur and is then removed. After saturation, V_{CD} is applied to the resistor R for the duration of the set half-cycle. The presence of R is necessary to prevent high-frequency oscillation after saturation. This oscillation is caused by the flux in the core dropping from its saturation to its remanance value. This sudden flux change in combination with the capacitance of the windings causes ringing which is amplified by the transistor to the point at which sustained oscillation occurs. By fixing R in conjunction with V_{CD} to give a current about equal to that flowing before saturation, the difficulty may be eliminated.

Evidently, circuit *2* has disadvantages not suffered by circuit *1:* 1. the transistor must pass the transformed load current, and, 2. power is wasted by R. In certain situations, however, these disadvantages may not be great.

The sequential set circuit proper consists of a series combination of the two basic circuits just described. A simplified 3-stage version, as illustrated in Fig. 3, will be described to introduce the basic mode of operation. Again it is assumed that reset has just been completed. Upon the application of the positive half-cycle of V_{CD}, there is a short transient burst of current and a small reversible change of flux in all cores;[2] the emitter-to-collector resistance of all transistors is momentarily lowered. However, the lowering of this resistance in the transistor of stage *1* means that less current and voltage is available for the succeeding stages. The condition is quickly established in which the first transistor is saturated, which means that only a few tenths of a volt of potential is available for causing flux change in the succeeding cores. This voltage is too small to cause magnetizing current to flow, so the last two stages are completely inactive. Thus, a constant-voltage output appears at the load winding of core *1* and is maintained until t_1, the time at which core *1* saturates. Upon the saturation of core *1*, transistor *1* goes to a high emitter-to-collector resistance value, so that V_{CD} is now applied to the remaining stages. By the same transient as before, stage *2* now becomes active. The voltage on the load of stage *2* is a flat-topped pulse extending from t_1 to t_2, the time of saturation of core *2*. By repetition of the same process, a voltage appears at the output of stage *3* from t_2 to t_3. Upon the saturation of core *3*, V_{CD}, less the IR drops in the set windings of all three cores, appears across the resistor R for the duration of the set half-cycle.

Three pulses are thus generated which always appear in sequence. If the resetting circuits of the three cores are independent of each other, and they may be made so by a means to be presently described, these three pulses may be made independent of each other in duration. The sole interdependence is that pulse *2* begins at the instant pulse *1* ends and pulse *3* starts upon the termination of pulse *2*.

When the supply voltage V_{CD} goes negative, the rectifier *CR4* blocks (this will be discussed more fully later on), as do the load rectifiers, and for the duration of the negative half-cycle the cores are reset by the input sources. On the subsequent positive half-cycle of V_{CD}, each core is set in turn, as previously described. Thus, the three different inputs are simultaneously sampled on one half-cycle, information as to the value of each input being stored in the corresponding core as a flux change, and this information is read out on the next positive half-cycle in time sequence as voltage pulses of variable width.

If the input sources represent voltages of continuously variable amplitude, the output pulses are continuously variable in width. The possibility of constructing a long delay circuit with a variable delay is worth noting. If an output were taken from the third core only, then this output could be shifted in time readily by varying the reset of cores *1* and *2*. In fact, the circuit could be simplified by combining cores *1* and *2* into a single core of large volt-second capacity.

The amplitudes of the output pulses are not flexible, since they are all derived

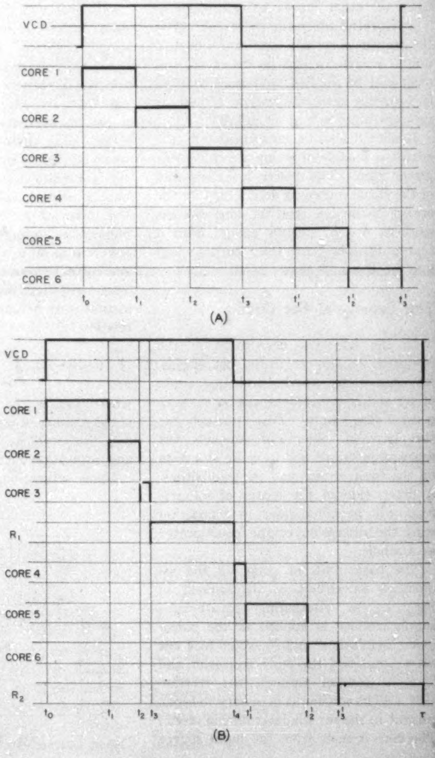

Fig. 4. Idealized output of a 2-bank 6-stage sequential set circuit

A—All cores are completely reset
B—Not all cores are completely reset. Core 1, full reset; core 2, 1/2 (of full) reset; core 3, 1/6 reset; core 4, 1/6 reset; core 5, full reset; and core 6, 1/2 reset

from V_{CD}. However, by varying the turns ratios of the load and set windings the pulses may be set at predetermined, but different, levels. In designing such a circuit, it is apparent that the total volt-seconds of the cores as viewed from the set windings must be less than, or equal to, the integrated volt seconds in one half-cycle of the supply voltage V_{CD}, i.e.,

$$\int_0^{T/2} V_{CD}dt = N_{S1}\Delta\phi_1 + N_{S2}\Delta\phi_2 + N_{S3}\Delta\phi_3 + \int_{t_3}^{T/2} I_sRdt,$$

where N_{S1} is the number of turns in the set windings of core *1*, N_{S2} the set turns on core *2*, etc., the $\Delta\phi$'s represent change in flux of the cores, and I_s is the current which V_{CD} causes to flow in the ballast resistor R. Or, replacing the fluxes by their volt-second equivalents,

$$\int_0^{T/2} V_{CD}dt = \int_0^{t_1} V_{CD}dt + \int_{t_1}^{t_2} V_{CD}dt \times \int_{t_2}^{t_3} V_{CD}dt + \int_{t_3}^{T/2} I_sRdt$$

By careful design, the last integral on the right may be made zero for the conditions of maximum reset of all three cores.

The objection that the sequential set circuit just described has a half-cycle of "dead" time may be eliminated by the addition of a second bank of three cores arranged to be set on the negative half-cycles of V_{CD}. The construction in so far as the set and base drive windings are concerned is identical with that of the first bank. The only difference is that the input from the supply is reversed. The first bank is set during positive half-cycles of the supply while simultaneously the second bank is being reset. On the negative half-cycles, the first bank is reset while the second bank is set. In Figs. 4(A) and 4(B), the outputs for such a double-bank arrangement are diagrammed for 1. the condition in which all cares are reset the maximum amount, giving a total volt-second value equal to that of the supply, and 2. in which core *1* has been completely reset, core *2* has been one-half reset, core *3* one-sixth reset, core *4* one-sixth reset, core *5* fully reset, and core *6* one-half reset.

Fig. 4(B) shows an inherent characteristic of a circuit in which the period of the supply is fixed and the reset of the cores is independently varied. After the application of the volt-seconds corresponding to a particular scheme of reset, the remainder of the volt-seconds in the supply half-cycle appears across the ballast resistor. Ordinarily, this interval represents useless "dead" time. However, situations might well arise in which use could be made of this pulse which occurs only after all stages have saturated.

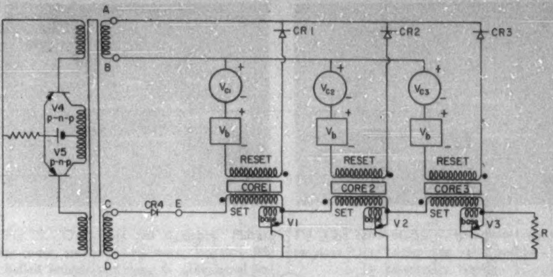

Fig. 5. Simplified 3-stage sequential set circuit showing method of accomplishing independent reset

The Commutating and Encoding Circuit

Various methods of accomplishing reset are possible. Fig. 5 shows a version of the method used in a 14-channel telemeter commutating-encoding system which will be described in detail later.

The supply source is a transistor saturable-core multivibrator. The circles labeled V_{c1} and V_{c2} are signal sources and may be either resistances or voltages. The rectangles labeled V_b are bias voltages (they may also be resistances) which were found necessary for this configuration. The need for them is made clear in the Appendix. The rectifiers *CR1*, *CR2*, and *CR3* will be discussed presently. The remainder of the circuit is identical with that of Fig. 3, except for the loads and load windings, which have been omitted for simplicity. The dots shown at the various winding ends are the conventional polarity indicators. Current into a dotted end takes the core toward positive saturation, current into an undotted end toward negative saturation. At a given instant on a particular core, all dotted ends have the same polarity. On the set half-cycle, terminals *A* and *C* are positive with respect to *B* and *D*. As core *1* sets, a voltage is induced in the reset winding of such a polarity as to unblock rectifier *CR1*. However, V_{AB} is set by design to hold the negative side of *CR1* more positive than the voltage generated by the reset winding, so that the reset winding is effectively isolated and can neither load the set circuit nor interact with any of the other resetting circuits. At the same time, rectifiers *CR2* and *CR3* keep V_{AB} from affecting cores *2* and *3*, since in these two stages there is no voltage induced in the reset windings. If the signal and bias sources are voltages, their polarity is in a direction opposite to the reset winding voltages; i.e., they help V_{AB} block the rectifiers. Since the voltage induced in any reset winding is zero under either 1. the condition of no current in the set winding, or 2. the condition of current in the set winding but with the core saturated, it is apparent that regardless of which cores are saturated, which is firing or which are yet to be fired, the reseting circuits are isolated from one another and from the voltage V_{AB}, except for rectifier leakage. With good semiconducting diodes, the leakage currents can be held to values well below magnetizing current, so that their effect is negligible.

When the set half-cycle is completed, the voltages V_{AB} and V_{CD} are reversed. V_{CD} is blocked by the rectifier *CR4*; V_{AB}, however, is in such a direction as to unblock rectifiers *CR1*, *CR2*, and *CR3*. This unblocking puts the three resetting circuits in parallel across V_{AB}. Resetting currents flow simultaneously from the bus at *B* through the control sources, the bias sources, the reset windings and the rectifier to the bus at *A*.

The fact that the cores are reset in parallel means that simultaneous voltages are induced in the set windings. Unfortunately, these voltages are in such a direction as to add, and if care is not exercised in design, their sum may be of sufficient magnitude to unblock rectifier *CR4* and throw a load on the resetting circuit. Suppose that the turns ratio of the set-to-reset windings is one, that $V_{AB} = V_{CD}$, and that all control and bias sources are zero, then the voltage at

the point *E* would be the sum of the individual voltages induced in the set windings, or $-3V_{CD}$, while the voltage at *C* would be $-V_{CD}$; clearly the rectifier would unblock.

In fact, there are three conditions which must simultaneously be satisfied for proper operation of the circuit: 1. The sum of the voltages induced in the set windings during reset cannot be greater than the supply voltage V_{CD}; 2. The total volt-seconds reset of the cores which takes place during the entire reset half-cycle must be less than or equal to the total volt-second capability of the supply voltage during the set half-cycle. 3. The voltage induced in the reset windings during the set half-cycle must not be large enough to unblock the reset circuit rectifiers.

These three conditions are stated analytically in the Appendix, and from them are derived the necessary design equations.

Telemetering Circuit

The circuit diagrammed in Fig. 6 shows an application of the sequential set circuit to telemeter encoding. Here a 2-bank sequential set circuit has been combined with a relatively high-frequency magnetic core multivibrator to obtain a 14-channel system.

The supply multivibrator operates at a frequency of 75.5 cycles per second, delivering a V_{CD} of 2.5 volts and a V_{AB} of 12 volts. The resistors *R1*, *R2*, ..., *R8* are the padding resistors referred to in the Appendix. The transducers *T1a*, *T2a*, ..., *T8a* are the control sources governing reset. In the circuit tested, they were resistors. The rectifiers marked *CR1a*, *CR2a*, ..., *CR8a* are the diodes used to isolate the reset windings during set. The rectifiers, *CR1c*, *CR2c*, ..., *CR8c* are diodes added in the collector circuits to prevent stage interaction during reset. Suppose, for example, that core *4* is not to be reset at all, but that cores *3* and *5* are to be reset the full amount. The positive voltage appearing at the undotted end of core *5* can feed through the resistance of R_{B1} to the bus connected to point *D*. In the absence of the rectifier *CR4c*, this positive voltage would be in the forward direction of the diode formed by the collector and base of *V4*, and resultant current flowing through the fourth stage base drive winding could partially reset core *4*. The positive voltage at the undotted end of core *3* would aid this effect because of back leakage through *V3*.

The high-frequency multivibrator drives the modulator. Built to operate in the range of 2 to 5 kilocycles, it takes advantage of the fact that, within limits, the fundamental frequency of such a multivibrator depends linearly on the voltage applied. The power sources are the load windings of stages 1, 3, 5, 6, and 8 feeding through the transducers (in this case, resistance) *T1b*, *T3b*, *T5b*, *T6b*, and *T8b*. The voltage applied to the high-frequency multivibrator is given by

$$V_{\text{app}} = \frac{N_L}{N_s}\left(V_{CD} - V_{T(b)} - I_L r_{(b)}\right)$$

Fig. 10. Same as Fig. 9, except that signal for stage 3 is at its maximum value, and core 2 is completely reset

where V_{Tib} is the voltage of the b transducer, and $I_L r_{ib}$ is the voltage drop across the corresponding b rectifier. The rectifiers *CR1b*, *CR3b*, etc. are provided to isolate the inactive stages from the active ones and to block voltages induced in the load windings during reset.

A typical output cycle is shown in Fig. 7. The initial high-frequency burst shown in the interval I to II has its duration controlled by transducer *T1a* and its frequency by *T1b*. Since these two are independent, the burst gives two channels of information. The blank period II to III is controlled by transducer *T2a;* thus, it affords a third channel. (It is perfectly feasible, and may be desirable in certain cases, to connect the output windings of stage *2* through a transducer to the high-frequency Royer. In this case, the wave train would be a succession of bursts of varying duration and frequency following each other so closely as to be practically continuous. Thus, our basic circuit would yield three more channels, for a total of 17.) In the interval III to IV, the high-frequency Royer is on for a period determined by transducer *T3a* at a frequency determined by transducer *T3b*. Thus, in general, the on and off times of the high-frequency Royer are made to convey information. The on times carry further information in the form of the frequency of oscillation.

The interval from VI to VII is the time during which the supply voltage V_{CD} is applied to the ballast resistor R_{Bf}. It may vary in magnitude from zero to practically the full half-cycle of the supply voltage. The interval X to XI is another such period. In this case, it affords a convenient method of "tagging" the cyclically repeating output, since it may be made longer than any other interval.

Since the supply source in itself is a multivibrator, and its frequency, and hence its period, depend on the voltage driving it, a measure of the period gives a measure of the voltage source driving it. Since the output of transducers frequently depends on the voltage source used with them, this information is useful and is counted as another channel. Thus we have a channel for each of the 13 transducers shown in Fig. 10 and an additional channel giving information on the voltage source, or 14 channels in all.

The intermodulation of the outputs of the sequentially set cores was checked by observing the change in one particular output pulse when all the other pulses were changed over their maximum range. A Tektronix *531* Scope was used. It was found that the intermodulation variation was less than the width of the oscilloscope trace for a total pulse width of 1.6 milliseconds. From the time scale and trace used, this is less than 1%.

Figs. 8, 9, and 10 show typical cases of the sequential circuit output. The multiplexed output using the high-frequency multivibrator is not shown, since it originated with Mr. Rochelle, who has discussed it elsewhere.[3]

Discussion

Though the circuit is flexible as to the number of stages which can be employed in each bank, it is difficult to predict what the limiting number might be. One apparent limitation is the resistive losses in the windings of the earlier stages. Use of large wire, few turns, and a high supply voltage would clearly permit the use of many more than the five stages tested. The more stringent limitation probably lies in the frequency limit of core switching with transistor drive. Suppose, for example, that the sampling (or frame) rate is high and the number of stages n is large. Then, since the time available to set a given core is $1/2f$ divided by n, or $1/2nf$, set may have to be accomplished in a microsecond or so, a time too short to be achieved by presently available components. Until this limitation can be overcome, a larger number of stages can be achieved only at the expense of a lower frame rate.

The frame rate is set by the fundamental frequency of the a-c supply. By present techniques, this rate can certainly be increased to a few kilocycles, provided the number of stages is not too large. A limitation here is the frequency capability of the a-c supply transistors, which in turn depends on the power they must handle.

Though the reset circuits shown draw the resetting voltage V_{AB} from a common supply, separate resetting voltage windings can be provided for each stage, thereby permitting either grounded or ungrounded input.

The possibility of using a synchronous decommutating circuit at the receiver end of a telemetering link presents problems. While it should not be hard to arrange for a synchronous multivibrator on the ground, the fact that the output of a given core follows immediately on the termination of the preceding one, which is pulse-width modulated, means that the output of a given channel does not occur at a fixed time in the frame. However, this difficulty can be overcome through the use of a diode-switching matrix and counters.

The output of the present circuit is similar to that of the commutating and encoding system to be used in the earth satellite.[3]

Conclusion

The sequential set circuit is seen to be basically an application of magnetic amplifier circuitry and as such displays the usual characteristics of such circuits. It handles direct voltages with facility, has a rather limited bandwidth, and the output occurs about one half-cycle later than the input. Considerable power gain is also possible, particularly when the internal impedance of the supply source

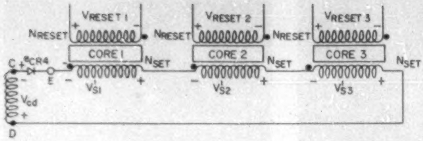

Fig. 11. The voltages in the set circuit during reset

is kept low. (The only inherent power limitation is in the transistors.) In conclusion, it may be stated that the components of the present circuit are reliable; the circuit itself is simple and is capable of being reduced to a small package which can be potted and hence made mechanically very rugged.

Appendix

The conditions which must be satisfied for proper operation of the circuit are stated here mathematically and from them are derived the necessary relationships between supply voltage, resetting voltage, control voltage, etc. This derivation is based on the assumptions that: 1. all stage cores are identical, and, 2. all biasing and signal sources are identical.

The biasing sources, though indicated as separate units, may represent the minimum (nonzero) values of the signal sources, or a combination of this minimum value and padding resistance or separate voltage sources. In this context, the signal voltages V_{ci} are understood to be the voltage in excess of the minimum voltage.

The usual first-order approximations, common in magnetic amplifier design, are made. That is, the magnetizing current I_m is assumed to be constant during a traversal of the hysteresis loop regardless of the voltage applied, and fixed rectifier and resistance drops are assumed.

Condition 1 is illustrated in Fig. 11 and may be stated as: The sum of the voltage induced in the set windings during reset cannot be greater than the supply voltage V_{CD}. V_{ri} is the voltage applied to the reset windings of the *i*th stage, V_{si}' is the voltage induced in the set windings of the *i*th stage, V_{CD} is the supply voltage, *eCR4* is the voltage across the blocked rectifier, N_s is the number of turns in the set windings, and N_r is the number of turns in the reset windings.

In equation form,

$$V_{CD}-(V_{s1}'+V_{s2}'+V_{s3}')=eCR4\geqq 0$$

or, in terms of the resetting voltages,

$$V_{CD}-\frac{N_s}{N_r}(V_{r1}+V_{r2}+V_{r3})=eCR4\geqq 0 \qquad (2)$$

For simplification, the assumption has been made that all set windings have the same number of turns and that all reset windings are identical.

Condition 2 is that the total volt-seconds reset of the cores which takes place during the entire reset half-cycle must be less than or equal to the total volt-second capability of the supply voltage, V_{CD}, during the set half-cycle.

Fig. 12 is an illustration of the resetting circuit of the *i*th stage during reset. Where V_{AB} = reset-source voltage, V_{bi} is the bias voltage, V_{ci} is the control voltage, V_{ri} is the voltage applied to reset windings, and V_{di} is the total voltage drop in rectifier and winding resistance.

By Kirchoff's law,

$$V_{AB}-V_{bi}-V_{ci}-V_{ri}-V_{di}=0$$

from which

$$V_{ri}=V_{AB}-V_{bi}-V_{ci}-V_{di} \qquad (3)$$

Clearly, V_{ri} is the maximum for V_{ci} equal to zero.

The flux change during reset is given by

$$\frac{1}{N_{ri}}\int_0^{T/2} V_{ri}dt=\frac{1}{N_{ri}}\times$$

$$\int_0^{T/2}(V_{AB}-V_{bi}-V_{ci}-V_{di})dt=\Delta\phi \qquad (3A)$$

For complete reset, V_{ci} is zero and

$$\frac{1}{N_{ri}}\int_0^{T/2}(V_{ri})_{\max}dt=\frac{1}{N_{ri}}\times$$

$$\int_0^{T/2}(V_{AB}-V_{bi}-V_{di})dt=2\phi_s \qquad (3B)$$

The cores are set individually as shown in Fig. 13, where V_{si} is the setting voltage, V_{CD} is the supply voltage, and V_t is the lumped transistor and rectifier drop. Summing voltages,

$$V_{CD}-V_{si}-V_t=0$$

$$V_{si}=V_{CD}-V_t$$

The volt-seconds absorbed by this core in the set half-cycle is

$$\frac{1}{N_s}\int_0^{t_1} V_{si}dt=\frac{1}{N_s}\int_0^{t_1}(V_{CD}-V_t)dt$$

Since the cores are read out in sequence, the total volt-seconds absorbed is

$$\frac{1}{N_s}\left[\int_0^{t_1}(V_{CD}-V_t)dt+\int_{t_1}^{t_2}(V_{CD}-V_t)dt+\int_{t_2}^{t_3}(V_{CD}-V_t)dt\right]$$

or

$$\frac{1}{N_s}\int_0^{t_3}(V_{CD}-V_t)dt \qquad (3C)$$

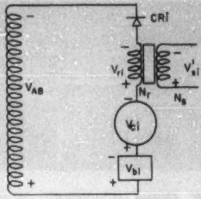

Fig. 12. The voltages in the resetting circuit of the ith stage during reset

It is evident that t_3 must be less than or at most equal to $T/2$; t_3 will have its maximum value when all cores have been reset by a maximum amount. As we have seen, this occurs when all the V_{ci} are zero; hence, using equations 3(B) and 3(C),

$$\frac{1}{N_s}\int_0^{T/2}(V_{CD}-V_t)dt$$

$$=\frac{1}{N_r}\sum_i^n\int_0^{T/2}(V_{AB}-V_{di}-V_{bi})\,dt$$

or

$$\frac{1}{N_s}\int_0^{T/2}(V_{CD}-V_t)dt=3/N_r\times$$

$$\int_0^{T/2}(V_{AB}-V_{di}-V_{bi})dt \qquad (3D)$$

Equation 3 (D) is the mathematical expression of condition 2.

Condition 3 is that the voltage induced in the reset windings during the set half-cycle must not be large enough to unblock the reset circuit rectifier. The resetting circuit and the voltages during set are diagrammed in Fig. 14, where V_{si} is the setting voltage, V_{ri}' is the voltage induced in reset winding during set, V_{ci} is the control voltage, V_{bi} is the bias voltage, e_{ri} is the voltage across blocked rectifier, and V_{AB} is the reset-source voltage. Summing the voltages gives

$$V_{AB}+V_{bi}+V_{ci}-V_{ri}'=eCRi\geqq 0 \qquad (4)$$

which is the equation for condition 3.

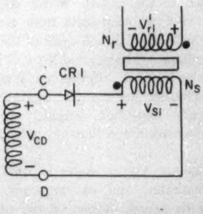

Fig. 13. The voltages in the set circuit of the ith stage during set

Vol.
Pt. 1
195

Thus, the three following equations must be satisfied:

$$V_{CD}-\frac{N_s}{N_r}(V_{r1}+V_{r2}+V_{r3})=eCR4\geqq 0 \qquad (2)$$

$$\frac{1}{N_s}\int_0^{T/2}(V_{CD}-V_t)dt=\frac{3}{N_r}\times$$

$$\int_0^{T/2}(V_{AB}-V_{di}-V_{bi})dt \qquad (3D)$$

and

$$V_{AB}+V_{bi}+V_{ci}-V_{ri}'=eCRi\geqq 0 \qquad (4)$$

We begin by comparing equations 2 and 3(D). By equation 3, and with the assumption that $V_{b1}=V_{b2}=V_{b3}=V_b$ and $V_{d1}=V_{d2}=V_{d3}=V_d$

$$V_{ri}=V_{AB}-V_b-V_{ci}-V_d$$

Before substituting this into equation 2, we note that the condition for equality of equation 3(D) is for the case of maximum reset, i.e., for $V_{ci}=0$.

$$V_{CD}-\frac{N_s}{N_r}[(V_{AB}-V_b-V_d)+(V_{AB}-$$

$$V_b-V_d)+(V_{AB}-V_b-V_d)]=eCR4$$

or

$$V_{CD}-\frac{3N_s}{N_r}(V_{AB}-V_b-V_d)=eCR4 \qquad (5)$$

To reduce equation 3(D), we take advantage of the fact that all the voltages are constant over the time of integration, so we may write

$$\frac{V_{CD}-V_t}{N_s}\,\frac{T}{2}=\frac{3(V_{AB}-V_b-V_d)T}{2N_r}$$

$$(V_{CD}-V_t)=\frac{3N_s}{N_r}(V_{AB}-V_b-V_d)$$

or

$$V_{CD}-\frac{3N_s}{N_r}(V_{AB}-V_b-V_d)=V_t \qquad (6)$$

Comparing equations 5 and 6, we see that they are identical if *eCR4* equals V_t. Since V_t is positive, *eCR4* is greater than zero, and these two conditions are satisfied. (Examining equation 2, we see that if *eCR4* is greater than zero for the maximum values of $V_{r1}+V_{r2}+V_{r3}$, it will always be greater than zero for any value of the sum less than the maximum.)

To compare equation 4 with equations 2 or 3(D), we proceed to put it into an equivalent form, again setting V_c equal to zero. Since equation 4 describes a situation which exists during reset, we note that by transformer action

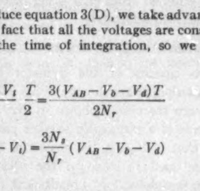

Fig. 14. The voltages in the reset circuit of the ith stage during set

$$\frac{V_{CD}-V_t}{N_s}=\frac{V_{ri}'}{N_r}$$

But by equation 4 $V_{ri}'=V_{AB}+V_b-eCRi$ substituting,

$$\frac{V_{CD}-V_t}{N_s}=\frac{1}{N_r}(V_{AB}+V_b-eCRi)$$

$$V_{CD}=\frac{N_s}{N_r}(V_{AB}+V_b-eCRi)+V_t$$

$$V_{CD}-\frac{N_s}{N_r}(V_{AB}+V_b-eCRi)=V_t \qquad (7)$$

Comparing equation 6 with 7, we see that we must have

$$\frac{3N_s}{N_r}(V_{AB}-V_b-V_d)=\frac{N_s}{N_r}(V_{AB}+V_b-eCRi)$$

Reducing and collecting terms,

$$2V_{AB}=4V_b-eCRi+3V_d$$

or

$$V_b=1/2V_{AB}+1/4eCRi-3/4V_d$$

If we require that the resetting rectifier be blocked by an amount equal to its forward drop (clearly an adequate condition when silicon rectifiers are used),

$$V_d=eCRi \text{ and } V_b=1/2(V_{AB}-V_d) \qquad (8)$$

Thus, the three simultaneous conditions for operation can be met by making V_b one-half of V_{AB} less the resetting circuit drops.

If a padding resistor R_b is to be used instead of the bias source *Vb*, the calculations must be modified slightly. Equation 4 becomes

$$V_{AB}+V_c-V_r'=eCRi\geqq 0 \qquad (4A)$$

since in setting it up we assumed no current flow, i.e., the rectifier blocked. Equations 5 and 6 are changed to the extent that V_b is replaced by I_mR_b, since in these equations magnetizing current flow was assumed. That is,

$$V_{CD}-V_t=\frac{3N_s}{N_r}(V_{AB}-I_mR_b-V_d) \qquad (6A)$$

Reducing equation 4(A) as we did equation 4,

$$\frac{V_{CD}-V_t}{N_s}=\frac{V_{ri}'}{N_r}$$

but $V_{ri}'=V_{AB}-eCRi$, since V_{ci} is zero, or

$$(V_{CD}-V_t)=\frac{N_s}{N_r}(V_{AB}-eCRi) \qquad (7A)$$

Thus we must equate

$$\frac{3N_s}{N_r}(V_{AB}-V_d-I_mR_b)=\frac{N_s}{N_r}(V_{AB}-eCRi)$$

Reducing and collecting,

$$2V_{AB}-3I_mR_b=3V_d-eCRi$$

$$3I_mR_b=2V_{AB}+eCRi-3V_d$$

Recalling that we have made $V_d=eCRi$, the result is

$$R_b=2/3\frac{(V_{AB}-V_d)}{I_m} \qquad (8A)$$

or R_b should be just 2/3 of the ratio of V_{AB} less V_d to I_m

Equations 8 and 8(A) are easily generalized to the case of *n* stages. Equation 8 becomes

$$V_b=\frac{(n-1)}{(n+1)}(V_{AB}-V_d) \qquad (9)$$

and equation 8(A) takes the form

$$R_b=\frac{(n-1)}{n}\,\frac{V_{AB}-V_d}{I_m} \qquad (9A)$$

Using the preceding equations, the explicit forms of the reset equation 3(B) can be written. If voltage bias is used,

$$\frac{1}{N_r}\int_0^{T/2}\left\{V_{AB}-\left[\frac{n-1}{n+1}(V_{AB}-V_d)\right]\right.$$

$$\left.-V_d\right\}dt=2\phi_s$$

and

$$\frac{2}{n+1}\,\frac{1}{N_r}\int_0^{T/2}(V_{AB}-V_d)dt=2\phi_s \qquad (10)$$

If resistance bias is used,

$$\frac{1}{N_r}\int_0^{T/2}\left\{V_{AB}-I_m\left[\frac{(n-1)}{n}\times\right.\right.$$

$$\left.\left.\frac{V_{AB}-V_d}{I_m}\right]-V_d\right\}dt=2\phi_s$$

and

$$\frac{1}{n}\,\frac{1}{N_r}\int_0^{T/2}(V_{AB}-V_d)dt=2\phi_s \qquad (10A)$$

The relation between supply voltage and reset-source voltage is found for the voltage bias case by substituting equation 9 into equation 6.

$$V_{CD}-V_t=n\frac{N_s}{N_r}\left\{V_{AB}-\right.$$

$$\left.\left[\frac{n-1}{n+1}(V_{AB}-V_d)\right]-V_d\right\}$$

$$\frac{V_{CD}-V_t}{N_s}=\frac{n}{n+1}\,2\frac{(V_{AB}-V_d)}{N_r} \qquad (11)$$

For resistance bias, we use equations 9(A) and 6.

$$V_{CD}-V_t=n\,\frac{N_s}{N_r}\times$$

$$\left\{V_{AB}-I_m\left[\frac{n-1}{n}\,\frac{(V_{AB}-V_d)}{I_m}\right]-V_d\right\}$$

$$\frac{V_{CD}-V_t}{N_s}=\frac{V_{AB}-V_d}{N_r} \qquad (11A)$$

To show the relations between signal voltage, reset-source voltage, supply voltage, and core flux, refer to equation 3(B). Maximum reset occurs for $V_{ci}=0$ and V_{ri} a maximum. The other extreme of no reset corresponds to $V_{ri}=0$, and by equation 3 must occur for

$$0=V_{AB}-V_b-V_c-V_d$$

or

$$V_{c\,\max}=V_{AB}-V_b-V_d$$

Putting in the value of V_b from equation 9 we have

$$V_{c\,\max}=V_{AB}-\frac{n-1}{n+1}(V_{AB}-V_d)-V_d$$

$$V_{c\,\max}=\frac{2}{n+1}(V_{AB}-V_d) \qquad (12)$$

A comparison with equation 10 shows that

$$\frac{1}{N_r}\int_0^{T/2} V_{c\,\max}dt=2\phi_s$$

Similarly, in the case for a padding resistor,

$$V_{c\,\max}=\frac{1}{n}(V_{AB}-V_d) \qquad (12A)$$

and

$$\frac{1}{N_r}\int_0^{T/2} V_{c\max}dt=2\phi_s$$

Relating V_c to V_{cb} through equations 11 and 12, we find

$$\frac{V_{CD}-V_t}{N_s}=n\,\frac{V_{c\,\max}}{N_r} \qquad (13)$$

for both bias voltage and padding resistor.

Linear Power Amplifiers Using Dynistors or Trinistors

FRANK J. HIERHOLZER, JR.
ASSOCIATE MEMBER AIEE

THE DEVELOPMENT of solid-state 2- and 3-terminal switching devices has made possible the design of physically small linear power amplifiers which have a large power-handling capability. Two- and 3-terminal switching devices will be referred to as "dynistors" and "trinistors" throughout most of this paper. Germanium dynistors and trinistors make excellent output devices for the linear power amplifier because: 1. The OFF state impedances are approximately 50,000 ohms; 2. The ON state impedances are approximately 0.05 ohm; 3. The dynistors and trinistors can be operated at much higher current densities than transistors; 4. The dynistors and trinistors need only a pulse to turn on. Once the dynistor or trinistor is on, the device can be turned off by reducing the current through it to a very small value. The characteristics of the germanium dynistor and trinistor are summarized in Appendix I.

The linear power amplifiers described in this paper use dynistors and trinistors as switches in series with the load or output. A magnetic amplifier is used as a transducer to translate input signal magnitude changes into electrical phase-angle changes. The voltage produced by the transducer at the electrical phase angle is impressed across a pulse network which passes the dynistor or trinistor turn-on pulse of current. The dynistors or trinistors turn off just before the current through the load becomes zero each half-cycle of the alternating current. Output waveforms from the dynistor or trinistor linear power amplifiers are very similar to those obtained from a magnetic amplifier.

This paper is limited to describing only two of the many possible magnetic-amplifier transducers and one of the many possible trinistor output circuits of the dynistor and trinistor linear power amplifiers. The output functions for both the dynistor and trinistor linear power amplifiers are defined in Appendix II.

Basic Theory of Operation

Either the dynistor or the trinistor linear power amplifier can be divided into three functional blocks. Fig. 1 shows the three blocks, which are: 1. the magnetic amplifier transducer, 2. the pulse network, and 3. the dynistor or trinistor output circuit. Because the dynistor and trinistor linear power amplifiers are somewhat different from each other, they will be described separately.

DYNISTOR LINEAR POWER AMPLIFIER

Two circuits of the dynistor linear power amplifier are shown in Figs. 2 and 3. Although the circuit shown in Fig. 3 can be made in a physically smaller package than that in Fig. 2, the circuit in Fig. 2 will be used to describe the operation of the amplifier. A breadboard model of the circuit which is shown in Fig. 2 was thoroughly tested at room temperature. Because the dynistors in the output circuit determine the design of the pulse network and the magnetic-amplifier transducer, the output circuit will be described first.

The output circuit consists of two diodes and two dynistors. The diodes and dynistors are arranged so that the output current does not flow through the control circuit. Each half-cycle of the alternating output voltage, one of the

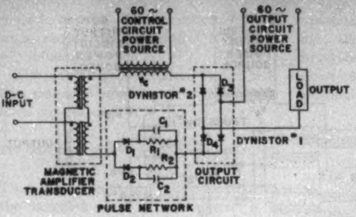

Fig. 2 (left). Dynistor linear power amplifier

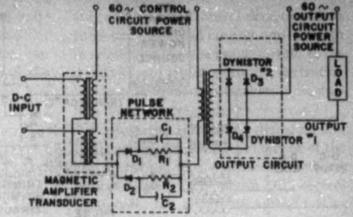

Fig. 3 (right). One possible variation for size reduction of dynistor amplifier

regular diodes shunts the output current by the control circuit. The regular diodes also shunt the control current by the output circuit. The peak value of the alternating output voltage must be less than the breakdown voltage (see Appendix I) of either dynistor. Very little load current (leakage and saturation current of the dynistor) will flow through the dynistors until the alternating control voltage turns on the dynistors. The peak of the alternating control voltage must be greater than the breakdown voltage of each dynistor. The firing angle shown in Fig. 4 is determined by the magnetic amplifier transducer but it has a maximum and minimum value determined by the alternating control voltage. If V_B is the breakdown voltage of each dynistor, then ϕ maximum and ϕ minimum are

$$\phi \text{ max} = \text{arc sin } \frac{V_B}{V_{c \text{ max}}}$$

where ϕ max $> 90°$; and

$$\phi \text{ min} = \text{arc sin } \frac{V_B}{V_{c \text{ max}}}$$

where ϕ min$<$90 degrees.

The percentage of each half-cycle over which the magnetic-amplifier transducer will have control is

$$\text{Per cent of control} = \frac{\phi \text{ max} - \phi \text{ min}}{180°}(100)$$

where ϕ max and ϕ min are firing angles given in degrees.

Because the breakdown voltage of each dynistor is determined by the peak of the alternating output circuit supply voltage, the per-cent control desired would determine the control circuit alternating voltage.

A pulse network is inserted in series with the dynistor output circuit and the magnetic-amplifier transducer. The pulse network must pass the voltage pulse created by the saturation of the magnetic-amplifier transducer. After one of the dynistors turns on or changes from the high-impedance state to the hyperconductive state, the pulse network limits the current in the control circuit. One half of the pulse network controls the control circuit current each half-cycle of the alternating control voltage after one of the magnetic-amplifier cores saturates. The capacitors in the pulse network must be large enough to remain essentially uncharged if one of the magnetic-amplifier cores saturates before the ϕ minimum angle is reached. When either core saturates before ϕ minimum, the dynistor will not turn on and the capacitor charging time constant would be

$$T_{\text{charging}} \approx \frac{V_B}{I_B} C_1 = \frac{V_B}{I_B} C_2$$

The charging time constant must be large in relation to the time of 1/8 cycle of the control voltage. One eighth of a cycle represents an approximation of the time which the control voltage takes to rise from zero to the breakdown voltage of the dynistor

$$T_{\text{charging}} = 10\ (1/480) \text{ seconds}$$

This fixes the minimum value of capacitance. Because the capacitor must be discharged each half-cycle through the resistor in parallel with it, the discharging time constant is

$$T_{\text{discharging}} = R_1C_1 = R_2C_2$$

$$T_{\text{discharging}} \approx (1/2))(1/120) \text{ seconds}$$

To make R_1 and R_2 as large as possible, the minimum value of capacitance should be used. Diodes D_1 and D_2 serve three purposes: 1. They prevent positive feedback from the capacitors to the magnetic amplifier; 2. They allow the capacitors to discharge each half-cycle; 3. They reduce the control circuit current. However, if the diodes D_1 and D_2 block before the end of the gating or output half-cycle of the magnetic amplifier, the linearity of the magnetic amplifier will be affected.

D-c input changes are translated to electrical phase-angle changes with the use of a magnetic-amplifier transducer. The magnetic amplifier must be designed to absorb the total volt-seconds of each half-cycle of the control voltage. Winding resistances of both the transformer and and the magnetic amplifier must be

$$2R_{WMA} + R_{WT} \approx \frac{V_{c \text{ max}} \sin \phi \text{ min} - V_B}{I_B}$$

where

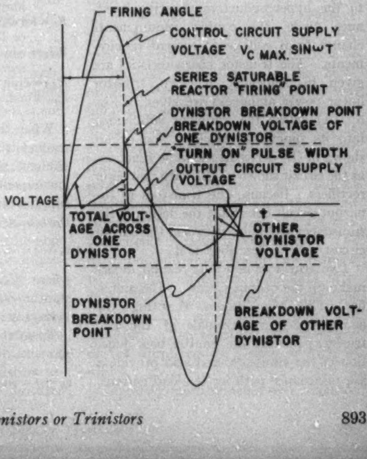

Fig. 4. Waveforms of dynistor linear power amplifier shown in Fig. 2, resistive load

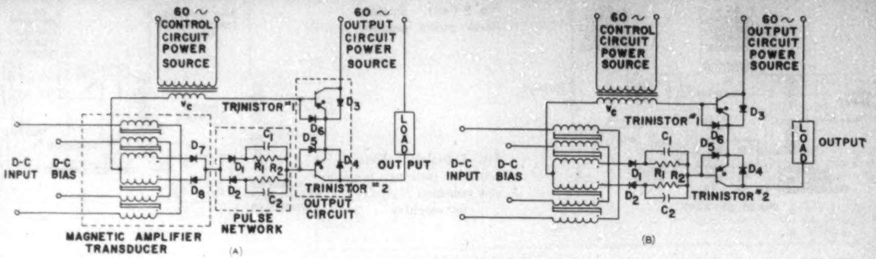

Fig. 5. Trinistor linear power amplifiers

R_{WMA} = winding resistance of the load or gate winding of one core
R_{WT} = winding resistance of the transformer secondary
I_B = dynistor current necessary for voltage breakdown
V_B = dynistor breakdown voltage

Linearity of the dynistor linear power amplifier is largely determined by the linearity of the magnetic amplifier. Because the dynistors have a maximum and minimum firing angle, the dynistor linear power amplifier will not be linear over the full half-cycle. The dynistor nonlinearities occur near the beginning and near the end of each half-cycle where the magnetic amplifiers are nonlinear. For linearity in the middle part of the transfer curve, both the control voltage and the output voltage waveforms should be the same. In other words, if one is a sine wave the other must be a sine wave also. Fig. 4 shows some of the amplifier waveforms near half output for a resistive load.

TRINISTOR LINEAR POWER AMPLIFIER

With the addition of a third electrode to the hyperconductive negative resistance diode, the control requirements change from voltage to current requirements. The trinistor characteristics are given in Appendix I. Two trinistor linear power amplifiers are given in Fig. 5; (A) shows the amplifier subdivided into its functional blocks. The circuit shown in (B) performs the same functions as the circuit shown in (A), with two fewer rectifiers. Because the trinistors in the output circuit determine the design of the transducer and pulse network, the output circuit will be described first.

Two trinistors and four regular diodes make up the output circuit of the amplifier. The two diodes shunting the emitter-collector terminals of the two trinistors protect the emitter-base junction of the trinistors, and also provide a low-impedance path for the load current. The two diodes shunting the base-emitter junction of each trinistor protect each emitter-base junction and provide a low-impedance path for control current. When base current equal to I_{b_s} flows in either trinistor, the breakdown voltage (see Appendix I) of the trinistor drops to zero. The maximum and minimum firing angles (see Fig. 6) can be determined by first plotting breakdown voltage versus base current and then obtaining an equation of breakdown voltage as a function of base current for the low breakdown voltage portion of the curve. For the trinistor this equation is

$$v_B = m i_{\text{base}} + C$$

where m and C are constants for a given trinistor.

The base current is

$$i_{\text{base}} = \frac{V_{c\,\max} \sin \phi}{R_{WMA} + 2R_R + R_{WT} + R_{EB}}$$

where

$V_{c\max} \sin \phi = V_{c\max} \sin \omega t$ = instantaneous value of control circuit voltage
R_{WMA} = winding resistance of magnetic-amplifier load winding
R_R = forward resistance of either D_1, D_2, D_5, or D_6 (assuming they are equal)
R_{WT} = winding resistance of transformer secondary
R_{EB} = emitter-base resistance of trinistor
i_{base} = instantaneous value of base current

When the output circuit supply voltage reaches the breakdown voltage of the trinistor, the trinistor will become a very low impedance. The equation for output supply voltage across the trinistor before the trinistor turns on is

$$v_0 = v_T = V_{0\,\max} \sin \phi$$

where $V_{\max} \sin \phi = V_{0\max} \sin \omega t$ = instantaneous value of the output source voltage across one trinistor.

To solve for ϕ minimum, equate v_T and v_B:

$$v_B = v_T = m i_{\text{base}} + C = V_{0\,\max} \sin \phi_{\min}$$

Substituting i_{base} in this equation yields

$$m\left(\frac{V_{c\,\max} \sin \phi_{\min}}{R_{WMA} + 2R_R + R_{WT} + R_{EB}}\right) + C = V_{0\,\max} \sin \phi_{\min}$$

$$\left(\frac{m V_{c\,\max}}{R_{WMA} + 2R_R + R_{WT} + R_{EB}} - V_{0\,\max}\right) \times \sin \phi_{\min} = -C$$

$$\phi \min = \text{arc} \sin \left(\frac{-C}{\dfrac{m V_{c\,\max}}{R_{WMA} + 2R_R + R_{WT} + R_{EB}} - V_{0\,\max}} \right)$$

Note that m is a negative quantity: ϕ minimum<90 degrees.

The equation for ϕ minimum will hold only if the capacitance in the pulse network is large enough so that the base current is determined by the control circuit resistance and instantaneous control voltage. This equation is also derived on the assumption that the cores of the magnetic amplifiers saturate before ϕ minimum and the inductive reactance of the cores after the cores saturate is negligible in comparison to the resistance in the

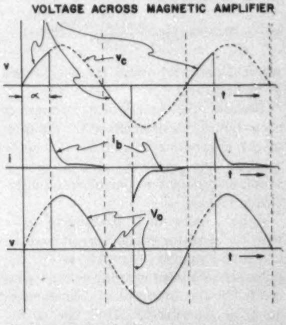

Fig. 6. Trinistor linear power amplifier waveforms, resistive load

control circuit. The maximum firing angle is equal to ϕ maximum $= 180$ degrees $-\phi$ minimum.

The percentage of each half-cycle which the magnetic-amplifier transducer will have control over is

$$\text{Per cent control} = \frac{\phi \max - \phi \min}{180°}(100)$$

Thus the per-cent control obtained with the magnetic-amplifier transducer is a function of the output voltage as well as of the control voltage and the control circuit resistance.

The pulse circuit in the trinistor linear power amplifier must be designed so that 1. the capacitors discharge during one half-cycle of the alternating control voltage; and 2. the charging current of the capacitors is greater than I_{bs} when the magnetic amplifier transducer saturates before ϕ minimum. Both the dynistor and trinistor linear power amplifiers have the same discharge time constants: $T_{\text{discharging}} = R_1C_1 = R_2C_2 \approx 1/2(1/120)$ seconds.

To make R_1 and R_2 as large as possible, the minimum value of capacitance should be used. This capacitance can be calculated using the following relationship:

$$Q = CV$$

$$\frac{\Delta Q}{\Delta t} = C\left(\frac{\Delta V}{\Delta t}\right) = i$$

where $\Delta V/\Delta t$ is the rate of change of the voltage with respect to time near ϕ minimum.

Using a straight line approximation for $\Delta V/\Delta t$ at small angles gives

$$\frac{\Delta V}{\Delta t} = \frac{V_{c\,\max}}{1/240}$$

$$\frac{\Delta V}{\Delta t} = 240\ V_{c\,\max}$$

Substituting $\Delta V/\Delta t$ in the equation for i gives

$$i \approx C(240\ V_{c\,\max})$$

but $i = I_{bs}$ if the trinistors are to turn on at ϕ minimum. Therefore the capacitance C_1 and C_2 is

$$C_1 = C_2 \approx \frac{I_{bs}}{240\ V_{b\,\max}}$$

The magnetic-amplifier transducer translates d-c input changes into electrical phase-angle changes. The discussion of the transducer in the section "Dynistor Linear Power Amplifier" applies to the trinistor linear power amplifier, except for the remarks concerning the winding resistance. The physical size of the magnetic-amplifier transducer is the limiting factor for the control voltage and load-winding resistance. The higher the control voltage, the larger the magnetic amplifier must be. Load-winding resistance can be decreased by increasing the size of the magnetic amplifier.

Discussion

The trinistor and the dynistor linear power amplifiers will be compared in this section. Linearity of both amplifiers with inductive and capacitive loads as well as resistive loads will be discussed. Although neither amplifier has been tested in ambient temperatures above and below normal room temperature, some temperature limitations will be given.

In both amplifiers the load or output current must be independent of the control current. This enables the control circuit of the amplifier to function independently of the output. Large power gains between the control circuit and the output circuit of the dynistors and trinistors are then possible. The actual power gain between the control circuit and the output circuit of the dynistor amplifier is approximately 20 db (decibels). This is less than the 45-db gain obtained in the trinistor amplifier because of the high voltage in the dynistor control circuit. Breadboard models of the dynistor amplifier had over-all power gains of approximately 45 db. Breadboard models of the trinistor amplifier had over-all power gains greater than 60 db. No attempt was made to optimize the gain of either amplifier.

High control circuit voltage in the dynistor amplifier also increases its physical size. The trinistor amplifier is about one tenth the size of the dynistor amplifier. The transformer and magnetic-amplifier transducer in the dynistor amplifier are much larger than those in the trinistor amplifier.

Both the amplifiers function best when the maximum output power is between 500 and 1,000 watts. This 1,000-watt limitation of the breadboard models is not an inherent limitation of the amplifier. One thousand watts is approximately the maximum power-handling capability of present dynistors and trinistors without forced cooling. When dynistors and trinistors which control more power are developed. the amplifiers will be able to control more power. At these output powers the load current is much greater that the sustaining current of the dynistors and trinistors. Because the sustaining currents of the dynistors and trinistors are low in relation to the load or output current, the dynistors and trinistors remain in the hyperconductive state after the pulse from the control circuiting turns them on. The load current must be high in relation to the sustaining current of the dynistors and trinistors for the derivation of the maximum and minimum conduction angles to be valid.

Because the germanium dynistors and trinistors used in the output circuit of the amplifiers will not operate in ambient temperatures much above 75 degrees centigrade, the maximum ambient temperature of these amplifiers would be less than 75 degrees centigrade. The minimum ambient temperature would be determined by the nonlinearity of the magnetic - amplifier transducer. The change of resistance of the copper windings would have to be compensated for by the use of a negative temperature coefficient thermistor in the magnetic-amplifier input winding circuit.

The magnetic-amplifier transducer used in the trinistor linear power amplifier is a better transducer than the series saturable reactor used in the dynistor linear power amplifier. With the use of the steady-state output functions given in Fig. 7 for the two transducers, a comparison of the two can be made. The firing angle of the dynistor linear power amplifier is dependent upon the impedance in the gate or load circuit of the magnetic amplifier. The pulse network in the gate circuit of the magnetic amplifier is a nonlinear impedance with will introduce nonlinearities into the transfer function of the dynistor amplifier. Magnetic-amplifier load resistance does not affect the firing angle of the transducer used in the trinistor amplifier.

Load power factor does influence the operation and linearity of either amplifier. If the load is capacitive and the time constant of the capacitor-charging circuit is much less than the period of 1/2 cycle of the output circuit supply voltage, the capacitor will charge up and the dynistor or trinistor will change to the high-impedance state. The output power will not be a linear function of the input power. With inductive and resistive loads, the amplifiers will have an output power which is a linear function of the input power. With inductive loads, output current continues to flow after the output circuit supply voltage passes through zero (the circuit becomes free wheeling). The dynistors and trinistors do not transfer to the high-impedance state until after the load current becomes less than the sustaining current of the dynistors and trinistors. The resistive load operation of the amplifiers is shown in Figs. 4 and 6.

breadboard models of the dynistor and trinistor amplifiers for both inductive and resistive loads. In the region of output powers from 10% to 90% of maximum output power, the dynistor linear power amplifier had a variation in linearity of ±6%, and the trinistor amplifier of approximately ±3%. The maximum output power of amplifiers when the linearity tests were made was 500 watts. No difference in linearity was noticed when the load was changed from a resistive to an inductive load with a power factor of 60% with either amplifier. The larger deviation from linearity of the dynistor linear power amplifier shows the nonlinearity introduced by the impedance change of the pulse network. No attempt was made to obtain the best possible linearity from either amplifier. Negative feedback from the output to the magnetic-amplifier transducer would improve linearity.

Conclusions

1. Line voltage variations will not affect the linearity of either amplifier appreciably. Negative feedback may be necessary to minimize changes in output when the line voltage of the trinistor linear power amplifier is changed.

2. Linearity of the two amplifiers is primarily dependent upon the linearity of the magnetic-amplifier transducer.

3. Both amplifiers perform best with the smallest permissible load impedance.

4. The trinistor linear power amplifier can be made physically smaller than the dynistor linear power amplifier.

5. Both amplifiers are much smaller than magnetic amplifiers with comparable maximum output powers.

6. Maximum linearity will be obtained with the use of magnetic-amplifier transducers similar to the one used in the trinistor linear power amplifier. The firing angle of the magnetic amplifier should not be a function of the impedance in the gating circuit of the magnetic amplifier.

7. Both amplifiers will have an output power which is a linear function of input power for both resistive and inductive loads.

Appendix I. Summary of Dynistor and Trinistor Characteristics

Dynistor Characteristics

The dynistor breakdown volt-ampere characteristic curve is shown in Fig. 8(A). Circuit symbols used to represent the dynistor with the polarities for the breakdown characteristic are shown in Fig. 8(B); the symbol to the right is not generally used in circuits but it is included to show the physical construction of the dynistor.[1]

To change from the high impedance or OFF state to the hyperconductive or ON state, the dynistor must have a voltage V_B across it, and a current I_B through it. Once the dynistor changes to the hyperconductive state, the dynamic resistance R_H of the dynistor is less than 0.1 ohm. A current through the dynistor equal to or greater than the sustaining current I_s must be present if the dynistor is to remain in the hyperconductive state.

Trinistor Characteristics

Fig. 9(A) shows the volt-ampere breakdown characteristic of the trinistor for various base currents. Two circuit symbols for trinistors are shown in Fig. 9(B); the symbol to the right gives a simplified picture of the physical construction of the trinistor.[1]

The base electrode of the trinistor provides a low-resistance path for base current which reduces the breakdown voltage V_B of the trinistor. When the base current is equal to I_{bs}, the breakdown voltage of the trinistor is reduced to zero. The trinistor will be in the hyperconductive or low-impedance state as long as a base current equal to I_{bs} flows. If the base current is reduced to zero, a current equal to or greater than the sustaining current I_s must flow in the collector circuit if the trinistor is to remain in the hyperconductive state.

Appendix II. Explanation of Output-Input Functions for Amplifiers

The output functions of the three functional blocks of each amplifier are given in Fig. 7. Trinistor and dynistor circuit outputs are given as the change in resistance with occurs when the magnetic-amplifier transducer fires. This change in resistance occurs if the magnitude of the pulses from the pulse network is large enough to turn on the dynistors or trinistors in the output circuit. Because these pulses will cause the dynistors or trinistors to change state, the output functions of both the dynistor and the trinistor output circuits are written as a function of the magnetic-amplifier transducer firing angle.

All output functions given represent steady-state conditions. The transient response of either the dynistor or the trinistor linear power amplifier is governed by the response of the magnetic-amplifier transducer. A low-gain fast-response magnetic amplifier can be used as a transducer to obtain fastest response. The equations will not be derived here, but each will be restated, the symbols explained.

Dynistor Linear Power Amplifier

MAGNETIC-AMPLIFIER TRANSDUCER

$\alpha =$ arc cos

$$\left(\frac{\pi N_i Z_L V_i}{V_{c\max}\, N_g R_i}-1\right)$$

$\alpha =$ firing angle of transducer
$V_i =$ input voltage to transducer
$Z_L =$ effective load impedance of magnetic amplifier
$N_i =$ number of input windings on each magnetic-amplifier core
$V_{c\max} =$ maximum control circuit voltage (magnetic-amplifier load circuit)
$N_g =$ number of gate or load windings on each core
$R_i =$ resistance in series with V_i and input windings of magnetic amplifier

This equation was derived assuming voltage reset of the magnetic amplifier.

PULSE NETWORK

$$V_D=\frac{V_B\left(1-\epsilon^{-\frac{\tau}{\omega}S}\right)\left(1-\epsilon^{-\frac{\pi}{\omega}S}\right)\epsilon^{-\frac{\pi}{\omega}S}}{S\left(1-\epsilon^{-\frac{2\pi}{\omega}S}\right)}$$

where

$V_D =$ control circuit voltage across the dynistors
$V_B =$ breakdown voltage of each dynistor
$\tau/\omega =$ turn-on time of each dynistor
$S =$ Laplace transform variable
$\omega =$ angular frequency of either control voltage or output voltage
$\alpha =$ firing angle of magnetic-amplifier transducer

DYNISTOR OUTPUT CIRCUIT

$$R_D=\frac{1}{S}\left[\frac{V_B}{I_B}+\left(\frac{V_B}{I_B}-R_H\right)\left(\frac{\epsilon^{-\frac{\pi}{\omega}S}}{1-\epsilon^{-\frac{\pi}{\omega}S}}\right)-\left(\frac{V_B}{I_B}-R_H\right)\left(\frac{\epsilon^{-\frac{\alpha}{\omega}S}}{1-\epsilon^{-\frac{\pi}{\omega}S}}\right)\right]$$

where

$R_D =$ instantaneous value of dynistor resistance in series with output or load
$V_B =$ breakdown voltage of dynistors
$I_B =$ breakdown current of dynistors
$R_H =$ dynamic resistance of dynistor in hyperconductive state
$\omega =$ angular frequency of control frequency
$\alpha =$ firing angle of magnetic-amplifier transducer
$S =$ Laplace transform variable

The equation for R_D neglects the minimum drop V_m across the dynistors in the hyperconductive state.

Trinistor Linear Power Amplifier

MAGNETIC-AMPLIFIER TRANSDUCER

$$2\alpha-\sin 2\alpha=\frac{4\pi N_g^2}{V_{c\max}^2}\,[G_i(N_iI_i-N_bI_b)+C]^2$$

where

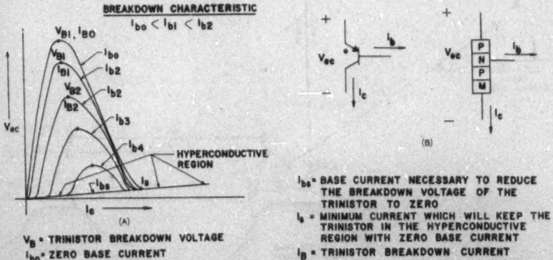
$\alpha =$ firing angle of magnetic-amplifier transducer
$N_g =$ number of gate or load windings on each core
$V_{c\max} =$ maximum control circuit voltage
$G_i =$ gain of core as determined empirically by Roberts test[3]
$C =$ constant determined by Roberts test
$N_i =$ number of input windings on each magnetic-amplifier core
$I_i =$ input current to magnetic-amplifier transducer
$N_b =$ number of bias turns on each magnetic-amplifier core
$I_b =$ bias current to magnetic-amplifier transducer

The equation for α was derived assuming constant magnetomotive force reset using an empirical equation containing contants which are evaluated using Roberts test values.[3]

PULSE NETWORK

$$I_b(S)=\frac{I_\alpha\epsilon^{-\frac{\alpha}{\omega}S}}{\left(S+\frac{1}{RC_1}\right)\left(1-\epsilon^{-\frac{2\pi}{\omega}S}\right)}-\frac{I_\alpha\epsilon^{-\left(\frac{\pi+\alpha}{\omega}\right)S}}{\left(S+\frac{1}{RC_2}\right)\left(1-\epsilon^{-\frac{2\pi}{\omega}S}\right)}$$

where



V_B = TRINISTOR BREAKDOWN VOLTAGE
I_{bo} = ZERO BASE CURRENT

I_{bs} = BASE CURRENT NECESSARY TO REDUCE THE BREAKDOWN VOLTAGE OF THE TRINISTOR TO ZERO
I_s = MINIMUM CURRENT WHICH WILL KEEP THE TRINISTOR IN THE HYPERCONDUCTIVE REGION WITH ZERO BASE CURRENT
I_B = TRINISTOR BREAKDOWN CURRENT

Fig. 9. A—Trinistor characteristics. B—Trinistor configuration: see note for Fig. 8(B)

I_α = peak value of pulse current
$I_\alpha = (V_{c\max} \sin \alpha)/R$
$R = R_{WMA} + 2R_R + R_{WT} + R_{EB}$

TRINISTOR OUTPUT CIRCUIT

$$R_T = \frac{1}{S}\left[\frac{V_{B0}}{I_{B0}} + \left(\frac{V_{B0}}{I_{B0}} - R_H\right)\left(\frac{\epsilon^{-\frac{\pi}{\omega}s}}{1-\epsilon^{-\frac{\pi}{\omega}s}}\right) - \left(\frac{V_{B0}}{I_{B0}} - R_H\right)\left(\frac{\epsilon^{-\frac{\alpha}{\omega}s}}{1-\epsilon^{-\frac{\pi}{\omega}s}}\right)\right]$$

where

V_{B0} = breakdown voltage of trinistor at zero base current
I_{B0} = breakdown current of trinistor at zero base current
R_H = hyperconductive state resistance of trinistor
R_T = instantaneous value of trinistor resistance in series with output or load

Over-all Output Functions

The over-all output-input functions are derived, assuming

$$R_H \ll R_L$$

$$\frac{I_B}{V_B} \gg R_L$$

$$\frac{V_{B0}}{I_{B0}} \gg R_L$$

DYNISTOR LINEAR POWER AMPLIFIER

$$P_0 = \frac{V_{0\max}^2}{2\pi R_0}\left(\pi - \alpha + \frac{\sin 2\alpha}{2}\right)$$

where

$$\alpha = \text{arc cos}\left(\frac{\pi N_t Z_L V_t}{V_{c\max}\ N_g R_t} - 1\right)$$

$V_{\max}$ = maximum voltage of output circuit power source
R_o = output or load resistance
P_o = output power

TRINISTOR LINEAR POWER AMPLIFIER

$$P_0 = \frac{V_{0\max}^2}{4\pi R_0}\left[2\pi - (2\alpha - \sin 2\alpha)\right]$$

where

$$2\alpha - \sin 2\alpha = \frac{4\pi N_g^2}{V^2_{c\max}}\left[G_t(N_t I_t - N_b I_b) + C\right]^2$$

The Expansion of the Pacific Coast Microwave Network

R. G. KUCK
NONMEMBER AIEE

THE PACIFIC COAST Microwave Development during the early formative years could hardly be considered a network in its own right. Although a relatively large use of microwave was planned at this time, the planning was limited to short systems with unquestionable economic advantages over competing facilities.

The initial microwave system installed in the United States for common carrier use provided eight voice channels between Santa Catalina Island, off the coast of Southern California, and the Mutual toll office in Los Angeles. Subsequently, a similar system was employed between Marysville and Redding, Calif. This early equipment was of Western Electric Company manufacture and carried the military designation of *AN/TRC-6*. It operated in the 4,500 to 4,800-mc (megacycle) band utilizing pulse position modulation. Originally designed for 8-channel service, some of these systems were later modified to provide 16 channels. Equipments of this type were continuously employed throughout the Pacific region from 1946 to 1954, and studies conducted on these systems helped pave the way for the future development of microwave communications in the area.

Following a testing program undertaken in the summer of 1946, the first installation of microwave for television transmission took place between Hollywood and Mt. Wilson, Calif., in 1947. Western Electric *TE-1* equipment operating in the then recently assigned allocation of 3,700 to 4,200 mc was installed to interconnect various Hollywood television studios and their transmitters atop 6,000-foot-high Mt. Wilson.

Early in 1948, a new series of tests was undertaken to determine the feasibility of broad-band multiple-section transmission. A number of *TE-1* microwave equipments were arranged as shown in Fig. 1. Both *L* carrier telephone multiplex and video test pattern signals were transmitted over this arrangement. One

of these tests involved an *A-B* comparison between long-distance circuits routed directly over an *L* coaxial cable carrier system and a second arrangement connecting the two facilities, microwave and coaxial in tandem. Numerous competent observers talked over these circuits under various traffic-loading conditions. The results were considered highly satisfactory.

Video tests were also conducted. A test pattern furnished directly from a pattern generator was fed through the 3-hop system. (The Mt. Woodson repeater was excluded from this test.) In an *A-B* presentation, the viewers were unable to detect any differences between the original pattern and that same pattern after transmission over the system.

These early installations and test programs paved the way for the broad-band developments to follow.

Later in 1948, an extensive investigation was initated, looking toward the establishment of a Los Angeles–San Francisco microwave route. This route was completed with nine repeater points between the Los Angeles and East Bay Hills areas. The repeater sections range from approximately 16 to 65 miles in length. These longer sections were in order of an experiment, for the nominal sections in use at this time rarely exceeded 35 miles.

As is so often the case, major routes are preceded by temporary or minor route installations. A case in point occurred in 1952. Early in the year, the company received an inquiry requesting television network facilities for a television station in Seattle, Wash. At this time, the video network had been extended from Sacramento, Calif., to Portland, Oreg., by means of an *L1* coaxial cable system, but no further. Although future plans called for a *TD-2* microwave system extension between Portland and Seattle, the normal installation period would have precluded the use of this system to meet the fall of 1952 request. This request was fulfilled by rushing the repeater site buildings to completion and collecting Western Electric *TE* type of equipment from throughout the Bell System. The *TE* equipment provided a temporary service until the originally planned *TD-2* equipment could be installed.

Recent Developments

The so-called major route development, once started, increased at a rapid pace to the extent that facilities are now operating from San Diego, Calif., on the south to Angeles Point, Wash., in the

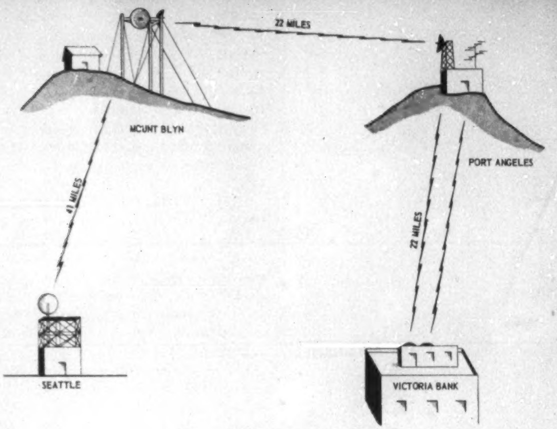

Fig. 3. Seattle–Victoria system

north. In addition, two major microwave routes now interconnect the Pacific Coast and the states in the Middle West and the East. They are the central route from the Bay area through Sacramento and east, and the southern route to Amarillo, Tex., from Los Angeles; see Fig. 2.

Paralleling the growth of long-haul major route facilities, the short-haul systems have also expanded at a rapid rate. These shorter systems operate mainly within the frequencies of 890 to 940, 3,700 to 4,200, and 5,925 to 6,425 mc.

Systems in this category employ a wide variety of equipments of various manufacturers. The original *AN/TRC-6* equipment has now been replaced with Radio Engineering Laboratories' 900-mc equipment and the islands of San Clemente and Santa Rosa have been linked to the mainland in like manner.

Numerous interesting solutions to difficult problems have been realized through the use of short-haul microwave systems. The following examples are more or less typical of the systems installed throughout the area.

In the far northern reaches of the state of Washington is an area known as the Olympic Peninsula. This area is generally primitive and therefore ideally suited for radio development. A microwave system was engineered to provide not only telephone growth to this remote area but to also supplant the then existing Seattle, Everett, Bellingham, Victoria cable, submarine cable, and open-wire composite route. The submarine portion of this latter facility had required almost continual repair because of armor wire abrasions.

On July 14, 1953, a 3-section system utilizing Lenkurt *72A* equipment with Lenkurt *33C* channelizing was placed in service; see Fig 3. The first two sections north of Seattle operate in the 900-mc band and the last section between Port Angeles, Wash., and Victoria, B. C., operates in the 450-mc band. The radio equipment is provided in full duplicate.

Based upon the experience gained from this installation and others in the area, an emergency radio system was placed in operation on December 1, 1957. This new system operates between Angeles Point and an Air Force installation at Neah Bay. It is interesting to note that, although the path is 55 miles in length and "over water," no stand-by or diversity arrangements were employed. The system provides eight circuits to the Neah Bay site in addition to those furnished by an open-wire and a buried cable route. This latter route parallels the highway serving the Neah Bay location; and unfortunately when earth slides disrupt the communication facilities, they also invariably block the highway, thereby complicating the facility restoration. This emergency system has removed the critical time element associated with plant repair while also improving the reliability of the circuits. These are examples where, by the use of radio, the communication services to an area of difficult accessibility have been materially improved.

The State of Oregon, like most of the area in the northwestern portion of the country, is divided by mountain ranges lying in a north-to-south direction. The population growth in the state has taken place mainly along the coast and in the valleys between these ranges. As a means of furnishing relief to the coastal area in the vicinity of Coos Bay, the West Coast Telephone Company and the Pacific Telephone and Telegraph Company jointly implemented a microwave system referred to as the Coos Bay–Eugene system; see Fig. 4. This combined effort was engineered with the use of three intermediate repeater locations designated Hauser, Canary Hill, and Mary's Peak.

The former is owned and operated by the West Coast Telephone Company and the latter two by the Pacific Company. Channel-dropping was employed at the Canary Hill repeater to provide circuits from Florence to Eugene in Oregon.

Between Eugene and Canary Hill, the system employs two regular channels and one stand-by, beyond Canary Hill the stand-by and regular channels are provided on a one-for-one basis.

In addition to the through systems, a short Hauser-Coos Bay system was subsequently installed for local service. This system wholly owned by the West Coast Telephone Company is operated without stand-by facilities.

The operation of this through system has demonstrated the ease with which an area formerly remote from the nationwide toll network was interconnected to it by the co-operative venture of the two serving telephone companies.

In May 1956, under agreement with the Department of the Interior, a completely overhauled and modernized telephone system was placed in service in Yosemite National Park; see Fig. 5. The open-wire lead which had served this area for many years was replaced by a 2-hop Lenkurt *72B* radio system operating between Merced, Fig. 6, and Turtle Dome (within the Park) by way of a repeater at Mt. Bullion; see Fig. 7. At Turtle Dome the circuits were extended to a new community dial office (CDO) in the Valley. In addition, a Motorola *MR-10* system was installed between Turtle Dome and Sentinel Dome. At this latter

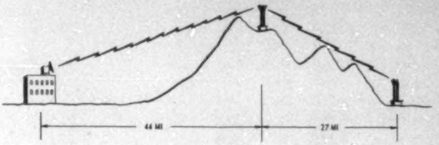
terminal, four circuits are interconnected to 450-mc point-to-point radio systems providing telephone service to the "high country." Like so many of the systems installed throughout the mountain regions, this particular installation has brought a service to the area comparable to that previously provided only in the heavily populated valley areas.

Another technique that demonstrates the flexibility of microwave transmission is the method by which a Yuma, Ariz., television station receives network programs; see Fig. 8. Although Yuma is approximately 230 airline miles from Los Angeles, off-the-air television service is provided with only one intermediate repeater. The television transmitters serving the Los Angeles area are located atop Mt. Wilson at an elevation of nearly 6,000 feet. After considerable investigation, a repeater site was chosen atop Mounument Peak, roughly 130 miles south of Mt. Wilson; see Fig. 9. This location in the Laguna Mountains area satisfies the two controlling requirements for a service of this type, namely, provides a line-of-sight path to both Mt. Wilson and Yuma, Ariz. The television signals, both video and aural, as received at Monument Peak are relayed over a Western Electric *TD-2* diversity microwave system to a television station at Winterhaven, Calif. The microwave path extends high over the Imperial Valley for a distance of approximately 100 miles, ending at the station's transmitter location. An 8-foot parabolic antenna is used at the mountain location and an 8-foot parabola–10- by 15-foot reflector combination is in use at the television station receiving location. This latter antenna system employs a nominal antenna-reflector spacing of 400 feet.

Over the years, microwave radio has passed from the status of a child of questionable reliability to an adulthood of performance comparable to any existing instrumentality. One example is the system now providing telephone service to Borrego, Calif. This Motorola System replaced an already heavily loaded open-wire lead requiring hazardous maintenance over 60 miles of uninhabited desert terrain. A portion of this lead traversed a naval-bombing and gunnery range.

Fig. 10. Borrego system



The citizens of Borrego receive telephone service exclusively over a 2-hop microwave system terminating at San Diego; see Fig. 10. Not only has service to the locale been substantially improved, but the maintenance hazards have been practically eliminated.

The foregoing examples are just a few of the continually expanding uses of microwave in the Pacific Telephone and Telegraph Company area to provide improvements in communication facilities.

In addition to these existing systems, the immediate future will see the realization of systems presently in the drawing-board stage. Among these will be a new north-south system between San Bernardino and the Wolf Creek repeater station east of Sacramento. This second microwave route along the length of California will be capable of carrying thousands of telephone circuits or their equivalent. It will provide access to many of the towns in San Joaquin Valley.

Probably the most spectacular program for microwave development in any area will be that contemplated within the state of Nevada. With the exception of a few isolated microwave installations, the State presently has no state-wide network as such.

Recent additions of toll facilities have taken place mainly by augmentation of existing open-wire and cable facilities. However, throughout the State, the unprecedented demand has severely taxed the existing facilities. With a continuing growth pattern anticipated in the near future, some form of fundamental relief was in order. This relief will be provided by microwave extending initially from Wennemucca in the north to Tonapah in the south.

The large cross-section portions of this system will employ Western Electric *TJ* and *TD-2* equipments while the side legs and short-haul sections will make use of Lenkurt units. One interesting feature of this state-wide network is the manner in which the terrain will be used to reduce the system costs. Many of the repeater sections approach 50 miles in length. As a means of improving transmission over such long paths, extremely high gain antennas are specified. The parabolas are 10 feet in diameter and will provide a gain of 41 decibels (11,000) relative to a half-wave dipole. This system will eventually be extended south to Las Vegas where interconnection to the existing Los Angeles–Amarillo route will be possible.

Many of the systems currently in the installation or planning stages will make use of Western Electric *TJ* equipment operating in the 10,700- to 11,700-mc band. The initial application of this equipment is in the Los Angeles area between the Grand Avenue toll office and a similar office in Compton, Calif. Although the path length of 12 miles is short by typical microwave standards, 10-foot parabolic antennas are being used. By providing excess system margins, the channelizing capabilities of the system will be substantially improved. Each microwave channel, so installed, should be capable of transmitting hundreds of voice circuits satisfying a heavy route requirement with short-haul equipments. This system will be used mainly to extend broad-band facilities now terminating at the Grand Avenue toll office to new terminals at the Compton location. In this manner, the circuits are being extended without the requirement for costly back-to-back terminal arrangements.

Conclusions

The period of the last 12 years has seen the expansion of microwave facilities at an almost unprecedented rate. This instrumentality in addition to being economically competitive, provides a flexibility and versatility previously unknown in the communications industry. The broad bandwidths available permit an almost unlimited choice of channelizing techniques. This feature, together with the multiple use of repeater stations, and the ability to modify systems or routes to meet new demands is difficult to assess on an economic basis. However, such flexibility is not being overlooked.

Vast amounts of new capital have been expended in the formation of this Pacific Coast microwave network. For the systems presently in operation the value exceeds 50 million dollars.

By the techniques already employed and those which the future holds, this network will no doubt continue to expand as one of the major methods of meeting the continuing demands for service within the Pacific Coast area.

Behavior of the Ferroresonant Series Circuit Containing a Square-Loop Reactor

R. H. DENNARD
ASSOCIATE MEMBER AIEE

Synopsis: An analysis is given for the behavior of the ferroresonant series circuit containing a reactor with 50% NiFe grain-oriented core material. Consideration is given to several different kinds (or modes) of steady-state circuit response at fundamental as well as at subharmonic frequencies for both sinusoidal and square-wave applied voltages. Conditions are derived which are necessary for the stable existence of these modes, and methods are given for the study of the transient processes by which these various steady-state modes are attained.

The dynamic magnetomotive-force requirements of the unsaturated reactor and the differential inductance of the reactor during saturation are represented with suitable approximations. Core test procedures are described which supply this magnetic information.

CIRCUITS combining capacitors and nonlinear inductors exhibit intriguing properties which have been discussed in the literature of the last 50 years. The simple series circuit of Fig. 1 has received particular attention. It is commonly called the ferroresonant series circuit since its bistable behavior was at first considered to be akin to resonance in linear systems. When this circuit is excited with a periodic applied voltage, the steady-state response takes different forms depending on the circuit parameters and on the initial conditions at the time the circuit is closed. This response may be at the same frequency as the applied voltage or at a subharmonic frequency, and the waveforms of current and voltages may or may not be symmetrical with respect to the time axis.

Literature Survey

Until recent years, the ferroresonant circuit contained reactors with core materials of "gradually varying" differential permeability. Analyses for this case have represented the magnetic properties by continuous functions approximating the normal **B-H** curve.[1,2] Many newer materials with greater remanence and sharply defined saturation levels are not suited for that kind of approximation, and representations in the form of straight-line segments have been introduced.

The idealized relationship between flux linkages ψ and current i of Fig. 2(A), with an infinite differential inductance in region (a) and a constant differential inductance in regions (b) and (c), has been used by Travis and Weygandt[3] in their study of subharmonics in the ferroresonant series circuit. The circuit resistance is omitted and the capacitor voltage is assumed to be negligible during saturation.

The approximation of Fig. 2(B), assuming zero differential inductance during saturation, has been applied by Salihi[4] to the study of a mode of operation with the same periodicity as the applied sinusoidal voltage. Brenner[5] uses the same assumption in his study of certain subharmonic modes of operation for various waveforms of applied voltage, modifying Fig. 2(B) by the introduction of a major hysteresis loop with fixed width and of minor loops as shown in Fig. 2(C).

Finally, Evans[6] uses the representation of constant magnetizing current for the unsaturated reactor and of constant permeability μ_0 (of free space) for the core during saturation. With these assumptions he studies a mode of operation having the same periodicity as the applied sinusoidal voltage. A similar approach for the case of zero magnetizing current is found in the unpublished work of R. L. Bright which was presented in a seminar at Carnegie Institute of Technology in 1953. The work of Bright contains the method of studying stability which is incorporated in this paper.

Method of Analysis

This analysis is concerned with values of the circuit parameters for which the inductance of the reactor during saturation and the magnetizing current of the unsaturated reactor have significant roles in the circuit operation. The magnetic properties of the reactor are represented as follows (see Fig. 3):

1. When $|\psi|<\psi_s$ the reactor is unsaturated and the magnitude of the magnetizing cur-

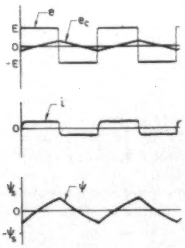

Fig. 4. Waveforms for low-current steady-state mode of operation with reactor A: 1,400 turns of no. 27 American Wire Gauge on 50% NiFe grain-oriented orthonol core of ID = 1 inch, OD = 1.25 inches, height = 0.25 inch, tape thickness = 0.002 inch; E = 17 volts, f = 400 cps, C = 0.1 μf (microfarad), R = 35 ohms

rent is taken to be a constant value I_u which may be evaluated from a core test in terms of the average rate of change of flux linkages, $d\psi/dt$.

2. When $|\psi|>\psi_s$ the reactor is saturated and the differential inductance $d\psi/di$ is an empirical single-valued function of i.

The method of analysis is to solve the circuit equation separately for the unsaturated and saturated conditions, and then to match the solutions at the points of transition.

Analysis for Square-Wave Applied Voltage

Unsaturated (Low-Current) Mode of Operation

When the applied voltage is sufficiently small, the reactor does not reach saturation and the circuit current is the relatively small magnetizing current. Waveforms for this case are shown in Fig. 4. The term iR is negligible in the circuit equation in the unsaturated condition for the values of resistance considered in this paper. Thus,

$$\frac{d\psi}{dt}=e-e_c \qquad (1)$$

using the sign conventions of Fig. 1. The average capacitor voltage during a half-cycle of the applied voltage is approximately zero, so the time integral of $d\psi/dt$ is simply $E/2f$ where E is the magnitude of the applied voltage and f is the frequency. This low-current mode of operation is possible as long as $E/2f$ does not exceed $2\psi_s$. The magnitude of E for which ψ alternates between $-\psi_s$ and $+\psi_s$ is called the "normal" voltage,

$$E_n=4f\psi_s \qquad (2)$$

As E is increased beyond the value E_n, the reactor must become saturated and the circuit operates in a different mode such as the basic high-current mode considered in the following.

Basic High-Current Modes

Fig. 5(A) shows waveforms for a mode of operation in which the circuit current is much larger than in the low-current mode. This is designated as a basic high-current mode because of its relative simplicity.

Consider the operation for an interval in which the reactor is unsaturated as between points *1* and *3* in Fig. 5(A). Equation 1 is valid and shows that $d\psi/dt$ is positive. The magnetizing current is fairly constant so the capacitor voltage increases linearly with time. (Notice, however, the abrupt change of i at point *2* where $d\psi/dt$ changes considerably due to a reversal of the voltage e.) The reactor remains unsaturated until ψ, changing at the rate $d\psi/dt=e-e_c$, reaches ψ_s at point *3*.

While the reactor is saturated ($|\psi|>\psi_s$), as between points *3* and *4*, the circuit behaves as a second-order oscillatory system composed of the saturated inductance, the capacitance C, and the resistance R which includes the winding resistance of the reactor. Actually, the differential equation which governs the circuit behavior is nonlinear since the differential inductance varies as a function of the current. The circuit behavior can be explained qualitatively, however, by assuming that the differential inductance has a constant value during saturation. With this assumption the current is a damped sinusoid which initiates at an almost zero value and has a large positive peak. When the oscillatory current reaches a small negative value at point *4*, the saturated condition is terminated. The saturation interval is short because the current oscillates at a high frequency. During this interval the capacitor voltage changes rapidly and reverses in polarity.

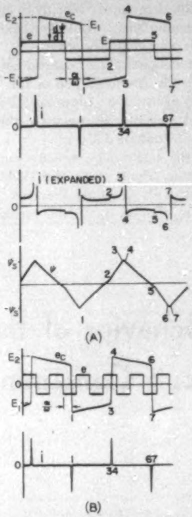

Fig. 5. Waveforms for basic high-current mode

A—At fundamental frequency: E = 17 volts, f = 400 cps, C = 0.1 μf, R = 35 ohms, reactor A

B—For third-order subharmonic: E = 7 volts, f = 400 cps, C = 0.5 μf, R = 20 ohms, reactor A

In the interval between points *4* and *6* the core flux reverses completely. The current is negative in the subsequent saturation interval, and at point *7* the conditions are the same as at point *1*. The operation continues in a cyclic manner.

A similar mode of operation, at a subharmonic frequency, is illustrated in Fig. 5(B) with the labeled points corresponding to the points described in the foregoing. The average magnitude of the reactor voltage, $e-e_c$, is much smaller and the reactor saturates only in every third half-cycle. Other modes of operation may exist in which the reactor saturates only every fifth, seventh, or *m*th half-cycle, where *m* is any odd positive integer and denotes the order of the subharmonic. These are called the basic subharmonic modes. Practical limitations determine a maximum possible value of m as will be shown, but values as large as $m=19$ have been observed experimentally.

A significant quantity which is designated by k and called the "overshoot factor" is here defined as the ratio of the magnitudes of $e-e_c$ just after and before saturation:

$$k=\frac{(e_c-e)_{t=t_u}}{(e-e_c)_{t=t_s}} \tag{3}$$

where t_s is the time at which saturation occurs and t_u is the time at which the reactor again becomes unsaturated. For the basic high-current modes, E_1 and E_2 are the magnitudes of the capacitor voltage just before and after saturation, as shown in Fig. 5, and thus

$$\frac{E_2-E}{E+E_1}=k \tag{4}$$

If the differential inductance during saturation may be approximated by a constant value L_s, then k is equal to $\exp\left(-\pi/\sqrt{(4L_s/R^2C)-1}\right)$. In reality, the differential inductance during saturation is a function of the current, and the value of the overshoot factor k depends on how far the reactor is driven into saturation. k is still a useful notation, and its realistic evaluation is discussed in detail in the next section.

The duration of saturation (which would be $\pi/\sqrt{(1/L_sC)-(R^2/4L_s^2)}$ for a linear saturated inductance L_s) is small in comparison with the unsaturated interval and will be considered zero. The average current I_u during the interval $m/2f$ when the reactor is unsaturated changes the capacitor voltage by the amount $mI_u/2fC$, hence

$$E_1=E_2-\frac{mI_u}{2fC} \tag{5}$$

Equations 4 and 5 give

$$E_1=\frac{1+k}{1-k}E-\frac{1}{1-k}\,\frac{mI_u}{2fC} \tag{6}$$

and

$$E_2=\frac{1+k}{1-k}E-\frac{k}{1-k}\,\frac{mI_u}{2fC} \tag{7}$$

The time integral of $d\psi/dt$ during the unsaturated interval must be $2\psi_s$, and thus

$$\frac{(E_1+E_2)}{2}\,\frac{m}{2f}-E\left(\frac{\pi-\alpha}{2\pi f}\right)+E\left(\frac{\alpha}{2\pi f}\right)=2\psi_s \tag{8}$$

where α is the "firing angle" at which saturation occurs.

These three preceding equations and the definition of equation 2 yield the equation

$$\frac{E}{E_n}=\frac{(1-k)+m^2(1+k)\left(\dfrac{I_u}{4fCE_n}\right)}{(m-1)+(m+1)k+\dfrac{2\alpha}{\pi}(1-k)} \tag{9}$$

relating the firing angle α and the nondimensional factors E/E_n, $I_u/4fCE_n$, and k.

Equation 8 is written with the assumption that the magnitude of the capacitor voltage decreases linearly during the unsaturated intervals. This is approximately true as long as $|e_c|$ is greater than e. It can be shown that this condition is met for any value of $0<\alpha<\pi$ as long as

$$\frac{I_u}{4fCE_n}\leq\frac{2k}{1+k},\ (m=1) \tag{10}$$

or

$$\frac{I_u}{4fCE_n}\leq\frac{k}{m^2(1+k)-k(m-1)-1},\ (m>1) \tag{11}$$

When this condition is met, the mode of operation is also found to be stable as shown in reference 7.

SATURATED INDUCTANCE AND EVALUATION OF k

Part of the flux linkages of the reactor comes from the field in the core material and part from the field in the media surrounding the magnetic core. The linkages of flux in the nonmagnetic media (of $\mu=\mu_0$) are represented as $\psi_0=L_0i$. The flux in the magnetic material contributes flux linkages $\psi_f=N\mathbf{B}_fA_f$ where N is the number of turns of the winding, A_f is the effective cross-sectional area of the toroidal core (as given in the catalogs of core manufacturers), and $\mathbf{B}_f$ is the average flux density normal to that area. The differential inductance is given by

$$\frac{d\psi}{di}=L_0+\frac{N^2A_f}{l_f}\,\frac{d\mathbf{B}_f}{d\mathbf{H}} \tag{12}$$

where l_f is the mean length of the flux path in the magnetic material and $\mathbf{H}$ is the field intensity Ni/l_f.

Fig. 6 shows the relationship during saturation between the differential permeability $d\mathbf{B}_f/d\mathbf{H}$ (relative to μ_0) and $\mathbf{H}$ for three samples of a certain core size. The curves were determined by measuring $d\psi/di$ and calculating $d\mathbf{B}_f/d\mathbf{H}$ from equation 12. The method of measurement was to bias the core into saturation, using a direct current from a high-impedance source connected across the core winding; a small alternating voltage was applied to a series circuit consisting of the same core winding, a known capacitance, and a resistance, and the differential inductance was found by determining the resonant frequency.

The saturated inductance for any reactor with the same core material can be represented by

$$\frac{d\psi}{di}=L_1+L_2g(i/I_2) \tag{13}$$

where $g(i/I_2)$ is a function which is unity for $i=0$ and approaches zero for large values of i. I_2 is a normalizing factor which is arbitrarily defined such that $g(1)=0.1$. Thus, $d\psi/di$ has the value L_1+L_2 for $i=0$ and approaches the value L_1 for large values of i.

A method of evaluating the overshoot factor k is given in Appendix I. The circuit relations are expressed in nondimen-

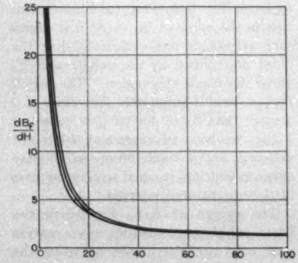

Fig. 6 (left). Relative differential permeability as function of field intensity for core of reactor A and for two other cores of same size

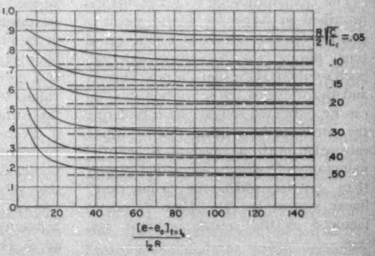
Fig. 7 (right). Overshoot factor k for reactor A; I_2 = 42 milliamperes for this particular reactor



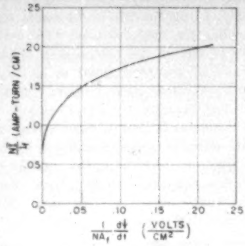


Fig. 8. Results of core test on reactor A for use in evaluation of I_u

sional terms, so as to maintain generality, and the resulting nonlinear differential equation is solved numerically. It is found that k depends on the magnitude of $e-e_c$ at the time of saturation, expressed in the nondimensional term $(e-e_c)_{t=t_s}/I_2R$, as well as on the parameters $(R/2)\sqrt{C/L_1}$ and L_2/L_1. Fig. 7 shows the calculated solution for the case of a particular reactor A having a typical value of L_2/L_1. The dashed lines represent the solution for the linear case in which $d\psi/di=L_1$. For large values of $(e-e_c)_{t=t_s}/I_2R$ it is recognized that **H** has a relatively large peak value during saturation, $d\psi/di$ is nearly L_1 for most of the time, and k is not much larger than for the linear case in which $d\psi/di=L_1$ during the whole saturation interval.

For the basic high-current modes

$$\frac{(e-e_c)_{t=t_s}}{I_2R}=\frac{E+E_1}{I_2R}$$
$$=\frac{2}{1-k}\left(\frac{E_n}{I_2R}\right)\left(\frac{E}{E_n}-\frac{mI_u}{4fCE_n}\right)\quad(14)$$

For a particular situation the value of k can be found by calculating $(e-e_c)_{t=t_s}/I_2R$ for an estimated value of k, locating the corresponding value of k from curves like those in Fig. 7, and repeating the process once or twice if necessary until the value of k found from the curve agrees with the estimated value.

The computation of k by the method described in Appendix I also yields a solution for the current as a function of time during the saturation interval. Such solutions show that the peak current and the width of the saturation interval can be estimated roughly by considering the circuit to be a linear system during saturation with a constant differential inductance of value L_e (somewhat greater than L_1) for which the "equivalent" linear system has the same overshoot factor k as the actual nonlinear system.

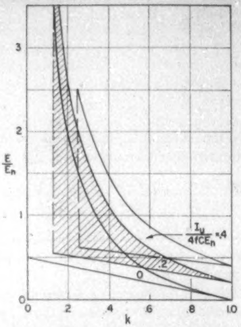

Fig. 9. Regions of parameters for which basic high-current mode is possible

EVALUATION OF AVERAGE MAGNETIZING CURRENT

The value of the average current during the unsaturated condition I_u may be determined from the results of a core test. For a given core it is accepted here that the instantaneous relationship between the magnetomotive force F, the flux ϕ, and $d\phi/dt$ is unique in processes of monotonic flux reversal initiated from pronounced saturation. This relationship can be found conveniently by the procedure of Feth,[8] keeping $d\phi/dt$ constant during flux reversal and measuring the average current I for the interval when the core is unsaturated. The results of such a test for many values of $d\phi/dt$ are given in the curve of Fig. 8; these results are plotted in terms of NI/l_f and $(1/NA_f)(d\psi/dt)$ so that the data can be used to predict the behavior of other cores of the same material and lamination thickness, and of the same ratio of the inside and outside core diameters (ID/OD).

When the ID/OD ratio is reasonably close to unity (about 0.8 or larger), F is fairly constant for a constant $d\phi/dt$, indicating that the influence of the time-varying ϕ is not particularly significant, and results such as shown in Fig. 8 may be used as an approximate instantaneous relationship between i and $d\psi/dt$. Hence in the problem at hand, I_u could be found by integration of the instantaneous values of i corresponding to the instantaneous values of $d\psi/dt$ for the interval in which the reactor is unsaturated. However, if the relationship between i and $d\psi/dt$ is almost linear over the range of variation of $d\psi/dt$, I_u can be approximated by the value of I corresponding to the average value of $d\psi/dt$. For the basic high-current modes the average value of $d\psi/dt$ during the unsaturated condition is $4f\psi_s/m$ and the corresponding values of I give accurate values of I_u as long as $d\psi/dt$ is somewhat greater than zero during the unsaturated interval. The values of I_u decrease for increasing values of m because of the smaller rates of flux change for the subharmonic modes of operation.

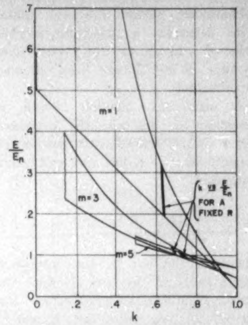

Fig. 10. Ranges of values of E/E_n and k for which various basic modes may occur ($I_u/4fCE_n=0.02$ for $m=1$). Variation of k as function of m and E/E_n is also given for the particular values $(R/2)\sqrt{C/L_1}=0.15$ and $(E_n/2I_2)\sqrt{C/L_1}=11.3$

RESULTS OF ANALYSIS FOR BASIC HIGH-CURRENT MODES

Summing up, it has been seen that the basic high-current modes of operation depend quantitatively on the nondimensional terms E/E_n, $I/_u4fCE_n$, and k. The overshoot factor k actually depends somewhat on the values of the other two terms except in situations where the reactor is driven far into saturation.

The range of parameters over which the basic high-current mode of Fig. 5(A) can exist is limited by the condition $0<\alpha<\pi$. This condition is used with equation 9 to determine the regions shown in Fig. 9. Consider, for example, that $I_u/4fCE_n=0.2$ so that the shaded region in Fig. 9 applies; to obtain operation in the mode of Fig. 5(A) it is necessary (although not sufficient) that the point determined by the values of E/E_n and k lies inside this region. The region for this case is given only for values of k greater than 0.11; for smaller values of k the condition of expression 10 is not satisfied, and a mode of operation may occur in which e_c is equal to e during part of the unsaturated interval.

The ranges of E/E_n for which the basic subharmonic modes of operation may exist are also found by using the condition $0<\alpha<\pi$ and equation 9. The

B—E=14 volts, f=400 cps, C=0.8μf, R=15 ohms, reactor A

C—E=22 volts, f=250 cps, C=0.8μf, R=10 ohms, 700 turns of reactor A

results are illustrated in Fig. 10 for values of k which satisfy conditions 10 and 11. The value of $I_u/4fCE_n$ is taken as 0.020 for $m=1$, and is reduced to 0.016 for $m=3$, and to 0.014 for $m=5$, to account for the smaller values of I_u in the subharmonic modes when the values of the frequency and the capacitance are fixed.

The heavy lines in Fig. 10 show how the overshoot factor k is related to E/E_n and to m for a particular set of circuit values. k is greater for the subharmonics because $e-e_c$ is smaller at the time of saturation. It is seen that for certain values of E/E_n the modes of $m=3$ and $m=5$ are both possible; the low-current mode of Fig. 4 is also possible (since $E/E_n<1$), so the circuit has at least three possible modes of steady-state operation.

The parameter $I_u/4fCE_n$ is particularly important for the subharmonics because of the relatively long unsaturated intervals in which the capacitor voltage decays due to the magnetizing current. Moreover, the average capacitor voltage is much smaller so the amount of decay $mI_u/2fC$ is a much greater percentage of the peak value E_2. Ultimately the rate of the capacitor discharge determines an upper limit on the possible values of m.

The average magnitude of the circuit current I_{av} is given by the relationship

$$\frac{I_{av}}{4fCE_n}=\frac{I_u}{4fCE_n}+\frac{1}{m}\left(\frac{1+k}{1-k}\right)\left(\frac{E}{E_n}-\frac{mI_u}{4fCE_n}\right) \qquad (15)$$

Fig. 11 shows the relationship between current and voltage for various values of resistance when the circuit is operating in the basic high-current mode at fundamental frequency ($m=1$). These curves are for a certain reactor and values of f and C such that $I_u/4fCE_n=0.2$. The curves were prepared by choosing many values of E/E_n and $(R/2)\sqrt{C/L_1}$, evaluating k, and calculating corresponding values of $I_{av}/4fCE_n$ from equation 15. The shaded region of Fig. 9 was used to determine the range of E/E_n for which the mode of operation is possible.

Fig. 11 also shows the average current for the low-current mode of operation. For the case of $(R/2)\sqrt{C/L_1}=0.5$, the circuit behavior is bistable when E/E_n is between the values 0.48 and 1.0. The dependence of the width of the bistable range on $I_u/4fCE_n$ and k is shown by Fig. 9.

The current "jumps up" to the high value when E is raised to just greater than E_n because, once the operation proceeds into the saturated region, the capacitor voltage builds up rapidly and forces the reactor far into saturation repeatedly. The current "jumps down" when the value of E is so low that the capacitor voltage cannot maintain a magnitude sufficiently large to give a resultant average reactor voltage of E_n over a half-cycle.

OTHER HIGH-CURRENT MODES OF OPERATION

A variety of other modes of operation are recognized in the experimentation, and some of these are illustrated in Fig. 12. When the applied voltage is considerably larger than the values for which the basic high-current ($m=1$) mode exists, the reactor becomes saturated twice in each half-cycle as shown in the waveforms of Fig. 12(A). Consider this operation starting first at point *1* where ψ has the value $-\psi_s$. The reactor is unsaturated between points *1* and *2* while ψ increases to $+\psi_s$. The volt-time integral indicated by the area A_1 is thus $2\psi_s$. The reactor is saturated between points *2* and *3*, and the capacitor voltage reverses polarity with respect to the applied voltage e during that time. In the interval *3* to *4*, ψ decreases by an amount equal to the area A_2; at point *4* the applied voltage reverses, changing the polarity of $d\psi/dt$, and ψ increases until the reactor again reaches positive saturation at point *5* which is determined by the condition $A_3=A_2$. In the saturation interval between points *5* and *6* the capacitor voltage again changes rapidly. The waveforms following point *6* are symmetrical to the waveforms starting at point *1*.

A very similar sequence of operation is found in the third-order subharmonic illustrated in Fig. 12(B). In fact, the labeled points correspond to the points described in the foregoing for the mode of Fig. 12(A). Higher order subharmonics also can exist in the same manner.

In the mode of operation illustrated by the unsymmetrical waveforms of Fig. 12(C) the reactor saturates twice in every other half-cycle of the applied voltage. Similar subharmonic modes of operation are also observed. For a certain range of voltages the modes of Figs. 12(A) and (C) are both possible; for somewhat higher voltages only that of Fig. 12(A) can occur and for somewhat lower voltages only that of Fig. 12(C) can occur.

All these modes of operation are investigated in more detail in reference 7, and several other modes of operation are discussed, including some even-order subharmonics. The same general method of analysis given for the basic high-current modes applies also to these many other modes of operation.

TRANSIENT ANALYSIS

The same principles used in the analysis of the steady-state operation of this circuit can be applied also to the study of transients by considering the behavior of the circuit step by step. This method lacks generality but is reasonably quick because the circuit response usually approaches the steady state within a few cycles of the response frequency.

When the circuit is abruptly closed there are three initial quantities which, along with the circuit elements and the applied voltage, determine the ensuing behavior. These quantities are the initial capacitor voltage $e_c]_0$, the initial flux linkages $\psi]_0$, and the phase angle $\Theta]_0$

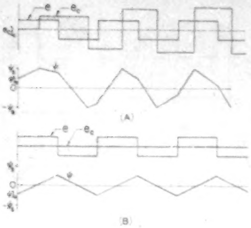

Fig. 13. Typical behavior after closing the circuit for case of E/E$_n$=0.5 and k=0.4

A—$\psi]_0>0$ B—$\psi]_0<0$

of the applied voltage at the time the circuit is closed. As an example, suppose that the circuit is closed with $e_c]_0=0$, $\Theta]_0=0$, and $E/E_n=0.5$. Fig. 13(A) illustrates the processes when $\psi]_0$ is positive under the assumption of negligible magnetizing current. The reactor must become saturated before the end of the first half-cycle in this case (because $\int_0^{\pi/\omega} e\,dt=\psi_s$,) and the time at which this occurs may be readily determined. During the first saturation interval the capacitor voltage rapidly builds up to a value $(1+k)E$ as determined from equation 3 which may be rewritten as

$$(e_c)_{t=t_u}=(1+k)e-k(e_c)_{t=t_s} \tag{16}$$

Subsequently, $e-e_c$ is negative and ψ decreases, reaching $-\psi_s$ at a time such that the shaded volt-time area is $2\psi_s$. The process continues in the same manner with the reactor saturating repetitively and the capacitor voltage builds up, almost reaching a steady-state condition after only 2 cycles of the applied voltage. In this process each firing angle and each value of e_c may be calculated successively. k may be evaluated for each saturation interval, but in this discussion of transients it is assumed that the values of $(e-e_c)_{t=t_s}/I_2R$ are such that k is practically a constant.

For the same conditions but with $\psi]_0$ negative, Fig. 13(B) shows that the reactor is never driven into saturation and the steady-state operation is the low-current mode. Thus it is seen that the initial conditions enter into the determination of the final steady state.

The type of transient shown in the example of Fig. 13(A) is not uncommon; i.e., it occurs frequently also with other initial conditions and circuit parameters. An analysis can be established rather easily in terms of difference equations if the tentative postulation is made that the reactor saturates once and only once in each half-cycle of the applied voltage. (For any particular set of parameters, the results obtained from equation 22 shall indicate whether or not this initial postulation is correct.) E_{c_0} is defined as the magnitude of e_c at the time the reactor is first saturated and α_1 is the corresponding firing angle. E_{c_0} and α_1 can be determined from $e_c]_0$, $\psi]_0$, and $\Theta]_0$ for a particular circuit and applied voltage. $\alpha_{(n)}$ is the firing angle in the nth half-cycle where $n=1$ designates the first half-cycle in which the reactor becomes saturated. It will be assumed that the capacitor voltage decays by the amount $I_u/2fC$ during each interval when the reactor is unsaturated, where I_u is evaluated as for the basic high-current ($m=1$) mode. The average magnitude of the capacitor voltage in the interval between $\alpha_{(n)}$ and $\alpha_{(n+1)}$ is designated $E_{c_{av(n)}}$ and is related to its previous value (for $n>1$) by

$$\left(E_{c_{av(n)}}+\frac{I_u}{4fC}-E\right)=k\left(E_{c_{av(n-1)}}-\frac{I_u}{4fC}+E\right) \tag{17}$$

For $n=1$:

$$E_{c_{av(1)}}=E+k(E-E_{c_0})-\frac{I_u}{4fC} \tag{18}$$

The solution to the difference equation 17 is

$$E_{c_{av(n)}}=E_{c_{ss}}\left[1-k^{(n-1)}\left(1-\frac{E_{c_{av(1)}}}{E_{c_{ss}}}\right)\right] \tag{19}$$

where $E_{c_{ss}}$ is the average magnitude of e_c in the steady-state of the basic high-current mode and is given by

$$E_{c_{ss}}=\frac{1+k}{1-k}\left(E-\frac{I_u}{4fC}\right) \tag{20}$$

The values of $\alpha_{(n)}$ may be determined from the volt-time area relationship:

$$E_{c_{av(n)}}(\pi+\alpha_{(n+1)}-\alpha_{(n)})-E(\pi-\alpha_{(n+1)}-\alpha_{(n)})=2\omega\psi_s \tag{21}$$

The fact that this difference equation is nonlinear discourages attempts at an analytical solution, but for any given case the successive values of $\alpha_{(n)}$ may be calculated from the following recursion formula derived from equation 21:

$$\frac{\alpha_{(n)}}{\pi}=\frac{1-\left(\frac{E_{c_{av(n-1)}}}{E_n}-\frac{E}{E_n}\right)\left(1-\frac{\alpha_{(n-1)}}{\pi}\right)}{\frac{E_{c_{av(n-1)}}}{E_n}+\frac{E}{E_n}} \tag{22}$$

The reactor saturates once and only once in each half-cycle as long as each value of $\alpha_{(n)}/\pi$ is between zero and unity, and this offers a check on the initial postulation.

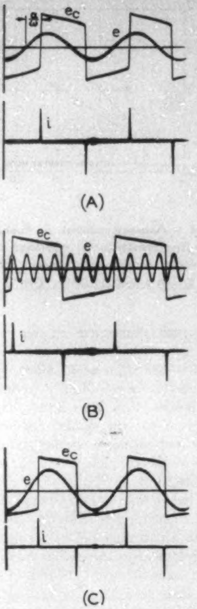

Fig. 14. Basic modes of operation with sinusoidal applied voltage

A—Symmetrical m=1 mode. E=11 volts (rms) f=400 cps, C=0.2 μf, R=15 ohms, 700 turns of reactor A
B—Symmetrical m=7 mode. E=3.2 volts, f=400 cps, C=5 μf, reactor A
C—Unsymmetrical m=1 mode. E=25 volts, f=400 cps, C=0.2 μf, R=15 ohms, 700 turns of reactor A

Equation 19 indicates that the steady-state operation is reached sooner for low values of k. As in the steady-state analysis, the assumption concerning the magnetizing current may be somewhat in error for low values of k but the conclusion is still valid. If $E_{c_{av(n)}}$ is plotted as a discrete function of t, where $t=n\pi/\omega$, it may be shown that the curve passing through these points is identical with the capacitor voltage in an R-C circuit with an applied voltage equal to $E_{c_{ss}}$ and with a value $E_{c_{av(1)}}$ at $t=\pi/\omega$ if the time constant τ of the R-C circuit is

$$\tau=\frac{\pi}{\omega\left[\log_e\left(\frac{1}{k}\right)\right]} \tag{23}$$

This curve approximates an envelope of the magnitude of the capacitor voltage

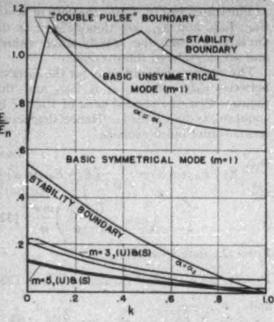

Fig. 15. Ranges of parameters for which basic high-current modes are possible in case of $I_u/4\sqrt{2}fCE_n=0$ for sinusoidal applied voltage

$|e_c|$ for the time following $t=\pi/\omega$, but does not necessarily give any indication of the behavior during the preceding time.

Analysis for Case of Sinusoidal Applied Voltage

The same general method of analysis may be used to study the behavior of the ferroresonant circuit for the case of a sinusoidal applied voltage, $e=E_m\sin\omega t$. Many of the modes of operation are qualitatively similar to the square-wave cases, but the analysis is more involved because the sinusoidal waveform leads to transcendental equations which are tedious to solve.

For this section the symbol E represents the rms value of the applied voltage and E_n is the rms value of the normal sinusoidal voltage ($E_n=4.44f\psi_s$). The low-current mode in which the reactor is unsaturated is possible as long as E is less than approximately E_n.

In the most common high-current mode of operation the reactor becomes saturated once in each half-cycle as shown in the waveforms of Fig. 14(A). During each interval in which the reactor is unsaturated, ψ changes from $-\psi_s$ to $+\psi_s$ or vice versa and the capacitor voltage decreases in magnitude while a small, nearly constant current of average magnitude I_u flows. During each short interval of saturation a relatively large peaked current flows and the capacitor voltage rapidly reverses polarity with respect to the applied voltage $E_m\sin\alpha$ at that time.

In the same manner, subharmonic modes of operation are possible for which the average reactor voltage during the unsaturated condition is so much smaller that the reactor saturates only in every mth half-cycle, where m is odd. An oscillogram for a seventh-order subharmonic of this kind is given in Fig. 14(B).

The waveforms shown in Figs. 14(A) and (B) are symmetrical with respect to the time axis. It is observed experimentally that larger values of the applied voltage may cause the waveforms to become unsymmetrical as illustrated by Fig. 14(C) in which different durations of the unsaturated condition are observed for positive and for negative capacitor voltages.

For the basic symmetrical modes of operation shown in Fig. 14 it can be shown that the firing angle α is related to the nondimensional terms E/E_n, $I_u/4\sqrt{2}fCE_n$, and k by the equation

$$\frac{E}{E_n}=\frac{(1-k)+\frac{m^2\pi}{2}(1+k)\left(\frac{I_u}{4\sqrt{2}fCE_n}\right)}{\frac{m\pi}{2}(1+k)\sin\alpha-(1-k)\cos\alpha} \qquad (24)$$

The overshoot factor k and the average magnetizing current I_u can be evaluated in the manner described for the case of a square-wave applied voltage.

A detailed analysis for the unsymmetrical cases is given in reference 7. The complex relationships cannot be presented in the space available here.

The stability of the symmetrical modes is investigated in Appendix II. It is found that these modes are stable as long as α lies in the range $\alpha_1<\alpha<\alpha_2$, where α_1 and α_2 are the values of α that satisfy equations 42 and 43 respectively. The ranges of applied voltage for which the symmetrical modes exist can be determined by using the stability criteria in conjunction with equation 24. The results are illustrated in Fig. 15 for the case in which $I_u/4\sqrt{2}fCE_n$ is negligibly small, and results for the unsymmetrical mode are also given. (The ranges of applied voltage which are given for the subharmonic modes cover both symmetrical and unsymmetrical operation.) When the capacitor voltage is smaller than the applied voltage during portions of the unsaturated intervals, the reactor is apt to become saturated more often than once each half-cycle; the new mode of operation is called a "double-pulse" mode, and this occurrence limits the ranges of the basic modes as indicated in Fig. 15.

Fig. 16 indicates the effect of the magnetizing-current discharge of the capacitor in the unsaturated intervals for the basic symmetrical modes of operation. The value of $I_u/4\sqrt{2}fCE_n$ is taken as 0.015 for the $m=1$ mode and is reduced to 0.012 for $m=3$ and to 0.011 for $m=5$ to account for the smaller values of I_u associated with the smaller rates of flux change in the subharmonic cases. The regions shown in Fig. 16 are limited to values of k for which the capacitor voltage remains greater in magnitude than the applied voltage during the unsaturated interval; thus the assumption that the magnetizing current is a constant value I_u is a good approximation. It is seen that the fifth-order subharmonic can exist for only a narrow range of applied voltages (corresponding to a narrow range of firing angles for which the mode is stable). For a certain set of circuit values, k is different in the three modes of operation as designated in Fig. 16.

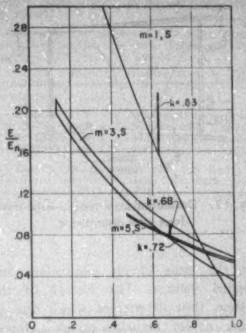

Fig. 16. Ranges of parameters for which basic symmetrical high-current modes are possible for sinusoidal applied voltage

Conclusions

The ferroresonant series circuit containing a square-loop reactor is an intriguing device in view of the large variety of possible modes of operation. The periodic steady-state operation can occur at the same frequency as the supply voltage or at a submultiple of that frequency, odd or even. One or more current pulses can occur within one half-cycle, and alternate half-cycles may or may not be symmetrical.

A detailed analysis has been given for the most common modes of operation, describing these modes quantitatively and determining the ranges of the circuit parameters for which these modes can exist in a stable manner. Overlaps of these ranges show the conditions for polystable operation, i.e., the conditions for which more than one mode can exist

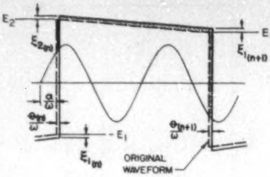

Fig. 17. **Deviations from steady-state waveform after disturbance**

for the same circuit parameters and applied voltage. The history of the system then determines which one of these modes actually occurs. Hence, methods of transient analysis have been given which allow the prediction of the eventual steady state when the capacitor voltage and the flux linkages are known at a given time such as the time at which the circuit is closed.

In the analysis that has been given, the dynamic properties of the reactor during flux reversal are accounted for by defining an average magnetizing current I_u which can be evaluated from the results of a core test. The magnetizing current is particularly significant when the capacitance is small or when the unsaturated interval is long as in many of the subharmonic modes.

The saturated inductance of the reactor is also a significant quantity for which no constant value can be assigned a priori. A method of measuring the saturated inductance is presented, and this leads to a realistic determination of the overshoot factor k in terms of the circuit components and the circuit voltages at the time saturation occurs.

Although the supply frequency used in the experimentation has been in the range of 60 to 1,000 (cycles per second), it appears that the analysis is valid also for much higher frequencies. It is noteworthy that all of the modes of operation found in the experimentation could be explained, or even predicted in advance, using the general concepts that have been established.

Appendix I. Evaluation of the Overshoot Factor k

The circuit equation is

$$(e-e_c)_{t=t_s}=\frac{1}{C}\int_0^t i\,dt+iR+\left(\frac{d\psi}{di}\right)\frac{di}{dt} \tag{25}$$

where time is measured from the beginning of operation in the saturated region ($t_s=0$) and e is considered constant for the duration of the saturated condition. Two nondimensional parameters are defined as follows:

$$x=\frac{t}{RC} \tag{26}$$

$$y=\frac{\frac{1}{C}\int_0^t i\,dt}{(e-e_c)_{t=t_s}} \tag{27}$$

With the use of these definitions and equation 13, equation 25 becomes

$$\frac{d^2y}{dx^2}\left\{1+\frac{L_2}{L_1}g\left[\frac{(e-e_c)_{t=t_s}}{I_2R}\frac{dy}{dx}\right]\right\}\frac{L_1}{R^2C}+\frac{dy}{dx}+y=1 \tag{28}$$

Define

$$\frac{dy}{dx}=z \tag{29}$$

From the previous definition it is seen that $z=iR/(e-e_c)_{t=t_s}$.

Then

$$\frac{dz}{dx}=\frac{4(1-z-y)\left(\frac{R}{2}\sqrt{\frac{C}{L_1}}\right)^2}{1+\frac{L_2}{L_1}g\left[\frac{(e-e_c)_{t=t_s}}{I_2R}z\right]} \tag{30}$$

The differential equation of the circuit has thus been reduced to two simultaneous first-order equations which are subject to the conditions $y]_{x=0}=0$ and $z]_{x=0}=0$ (corresponding to $1/c\int_0^t i\,dt=0$ and $i]_{t=0}=0$). y and z as functions of x can be found by numerical solution of equations 29 and 30 for particular values of $(R/2)\sqrt{C/L_1}$, $(e-e_c)_{t=t_s}/I_2R$, and L_2/L_1, and for a particular function $g(i/I_2)$.

Using equation 27 with the definition of k (equation 3), one finds that

$$k=\frac{(e_c)_{t=0}+(e-e_c)_{t=0}(y)_{t=t_u}-e}{e-(e_c)_{t=0}}=(y)_{t=t_u}-1 \tag{31}$$

From the values of y and z as functions of x, $(y)_{t=t_u}$ may be found as the first peak value of y (at $z=0$).

Appendix II. Stability Criteria for the Symmetrical Basic Modes of Operation; Sinusoidal Applied Voltage

The stability of the modes of operation illustrated in Figs. 14(A) and (B) is studied by considering the effect of a very small disturbance on the system while the circuit is operating in one of the modes under consideration. The firing angle and the capacitor voltage are changed by small amounts. Operation is stable if the system reverts to the same steady state after removal of the disturbance.

Let the nth firing angle after the disturbance be $\alpha_{(n)}=\alpha+\Theta_{(n)}$, and let the magnitudes of the capacitor voltage before and after saturation be $E_1+\xi_{1(n)}$ and $E_2+\xi_{2(n)}$ as illustrated in Fig. 17 for the case of $m=3$. $\Theta_{(n)}$, $\xi_{1(n)}$, and $\xi_{2(n)}$ are thus defined as the deviations from the steady-state values, and are considered infinitesimal.

The average value of $e-e_c$ for the interval between $\alpha_{(n)}$ and $\alpha_{(n+1)}$ is $2\psi_s$, and this requires that the shaded area of Fig. 17 be equal to the dotted area. Hence, neglecting second-order infinitesimals,

$$\frac{\Theta_{(n)}}{\omega}(E_2-E_m\sin\alpha)=\frac{\Theta_{(n+1)}}{\omega}(E_1+E_m\sin\alpha)+\left(\xi_{2(n)}+\frac{I_u}{C}\frac{\Theta_{(n)}}{\omega}\right)\frac{m\pi}{\omega} \tag{32}$$

From the definition of k

$$E_2-E_m\sin\alpha=k(E_1+E_m\sin\alpha) \tag{33}$$

and

$$E_2+\xi_{2(n)}-E_m\sin(\alpha+\Theta_{(n)})=k[E_1+\xi_{1(n)}+E_m\sin(\alpha+\Theta_{(n)})] \tag{34}$$

Since $\Theta_{(n)}$ is infinitesimal,

$$\sin(\alpha+\Theta_{(n)})=\sin\alpha+\Theta_{(n)}\cos\alpha \tag{35}$$

These last three equations yield the relation

$$\xi_{2(n)}=k\xi_{1(n)}+(1+k)E_m\Theta_{(n)}\cos\alpha \tag{36}$$

The capacitor voltage discharges at the rate I_u/C in each unsaturated interval; thus equation 5 is valid for the steady-state mode, and also

$$\xi_{1(n+1)}=\xi_{2(n)}-\frac{I_u}{\omega C}(\Theta_{(n+1)}-\Theta_{(n)}) \tag{37}$$

Substituting the value of $\xi_{1(n)}$ from equation 37 (with $n=n-1$) into equation 36, one finds

$$\xi_{2(n)}=k\xi_{2(n-1)}-k\frac{I_u}{\omega C}(\Theta_{(n+1)}-\Theta_{(n)})+(1+k)E_m\Theta_{(n)}\cos\alpha \tag{38}$$

Equation 32 can be solved for $\xi_{2(n)}$ (and $\xi_{2(n-1)}$), and substitution of these values into equation 38 yields a second-order difference equation in terms of $\Theta_{(n)}$. Equations 5 and 33 may be used to eliminate E_1 and E_2, giving the result

$$\Theta_{(n+1)}+2(A-k)\Theta_{(n)}+k^2\Theta_{(n-1)}=0 \tag{39}$$

where

$$A=\frac{m\pi(1-k^2)\frac{E}{E_n}\cos\alpha+2(1-k)^2\frac{mI_u}{4\sqrt{2}fCE_n}}{4\left(\frac{E}{E_n}\sin\alpha-\frac{mI_u}{4\sqrt{2}fCE_n}\right)} \tag{40}$$

The stability of this mode of operation is determined from the roots of the auxiliary equation

$$M^2+2(A-k)M+k^2=0 \tag{41}$$

Operation is stable as long as the roots M_1 and M_2 are less than unity in magnitude. A detailed examination (using the value of E/E_n from equation 24) shows that operation is stable for $\alpha_1<\alpha<\alpha_2$ where α_1 and α_2 are determined from

$$\tan\alpha_1 = \frac{\dfrac{m\pi}{2}\left(\dfrac{1-k}{1+k}\right)+\dfrac{mI_u}{4\sqrt{2}fCE_n}\times\left[\left(\dfrac{m\pi}{2}\right)^2-1-\left(\dfrac{1-k}{1+k}\right)^2\right]}{1-\dfrac{m\pi}{2}\left(\dfrac{1-k}{1+k}\right)\left(\dfrac{mI_u}{4\sqrt{2}fCE_n}\right)} \tag{42}$$

and

$$|\tan\alpha_2| = \frac{m\pi}{2}\left(\frac{1+k}{1-k}\right),\ \left(\alpha_2>\frac{\pi}{2}\right) \tag{43}$$

A New Small Crossbar Telephone System for Private Branch Exchanges

H. H. ABBOTT
MEMBER AIEE

A NEW small crossbar telephone system called the *756A* private branch exchange (PBX) was recently developed for business establishments requiring no more than 60 lines to PBX telephone stations and ten trunks to a telephone central office. Distinguishing features of this new PBX are the small size and attractive appearance of the cabinets for the PBX attendants and the switching equipment. These cabinets have colors and finishes that blend with modern office decor so they can be located satisfactorily adjacent to office furniture.

The floor space occupied by this PBX is smaller than that of earlier designed PBX's of comparable size. The PBX equipment assemblies include plugs and jacks on the interconnecting wires to simplify the work of installing, to shorten the interval from request for service until cutover, and to facilitate the removal and reuse of the equipment in different locations.

The switching equipment is housed in a cabinet as shown in Fig. 1. The cabinet consists of two modules with three slide-in units in each module. It can be furnished in two sizes, one for 40 lines and the other for 60 lines. Growth from the smaller to the larger size can be accomplished by unplugging the right-hand module and substituting another module more fully equipped.

The PBX attendant's equipment usually provided is a console of modern attractive appearance shown in Fig. 2. A cord-type switchboard can be provided for the attendant instead of this console or in addition to it according to the customer's service requirements. A key telephone set, shown in Fig. 3, can be provided remote from the other attendant's equipment, such as at a night watchman's station, to enable the watchman to complete calls during periods of light traffic when the regular attendant is off duty.

Customer Service Features

The service features from the customer's viewpoint are basically the same as those of earlier designed PBX's but are augmented by new arrangements to improve the speed and convenience. An important improvement is the "camp-on" feature. This is provided on incoming calls from the central office to PBX stations when the stations are busy.

An incoming call is indicated by a flashing lamp and an audible signal. To answer this call, the attendant presses a button and lifts her handset to talk. To complete the call, the attendant presses the HOLD button momentarily and then dials the 2-digit number of the desired station. If the station is free, the bell of the station is rung automatically. However, if the station is busy, the camp-on feature comes into operation. This causes the outside calling party to camp on the line to the station and, when the line becomes free, to be automatically connected through to the station immediately without any further attention from the PBX attendant. This assures to the calling party a priority on the busy line and the fastest possible completion of his call. If, while one outside party is camped on a busy station line, a second outside party calls the same line, the second party does not camp on the line and the PBX attendant receives a distinctive signal so that she can report the situation to the calling party.

After a connection has been completed from a trunk to a station, the station user can recall the PBX attendant, for a purpose such as transferring the call to another station, by only a single momentary depression of the station switchhook button. This will cause a flashing signal before the PBX attendant until the attendant answers. Then the attendant

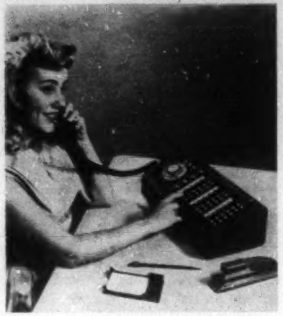

Fig. 2. PBX attendant's console

can proceed with the call as requested by the station user.

When the station user restores his handset without recalling the PBX attendant, the handset depresses the switchhook button continually and, after about one second, the path through the switches is automatically disconnected. The disconnect supervisory signal from the depressed switchhook is delayed in its transmission to the central office via the trunk until the expiration of this one-second interval. This is called the "delayed through supervision" feature.

A call from a PBX station to another PBX station is completed by dialing the 2-digit number of the called station.

Two or more up to a maximum of ten station lines can be arranged in a hunting group so that a call that is directed to one of the lines when it is busy will automatically be connected to one of the other lines in the same group, if one is idle. The numbers of the lines in the hunting group can be either consecutive or nonconsecutive with the same tens digit. The hunting can be optionally two-way or one-way. If it is two-way, a call dialed to any number in a hunting group will hunt to any other number in the same group regardless of whether the other number is higher or lower than the number dialed. If the hunting is one-way, it can be optionally hunted from low to higher numbers, or from high to lower numbers. For one-way hunting, diodes are connected, instead of strap wires, between successive terminals of lines in the hunting group; and the hunting is in the direction of the flow of current through the diodes.

A call from a PBX station via the central office to another station can be completed by dialing the digit 9, waiting for second dial tone from the central office, and then dialing the regular central office number. However, any station line can be restricted from completing such calls. When a line is restricted, a party who dials 9 from the station on this line will hear busy tone instead of the central office dial tone. This restricted service is effective only on outgoing calls dialed directly without assistance from the PBX attendant. The attendant can complete all incoming calls to restricted lines. The calling party can be connected from a restricted line to the central office by dialing 0 instead of 9 and, when the PBX attendant answers, requesting her to complete the connection. Such a connection can be completed while the calling party remains on the line with his handset off-hook.

If the central office is arranged to provide "toll diverting service," any *756A* PBX station line can be restricted from direct dialing of outgoing toll calls without being restricted from local calls. The methods of providing toll diverting service in the various types of central offices, and the limitations of this service in connection with nation-wide direct distance dialing, are beyond the scope of this paper.

When a toll call is completed by the PBX station dialing directly to the toll operator, the connection is held jointly by the station and the operator so that the station can recall the operator and the operator can ring back to the station. Such a ring back will not signal the PBX attendant. However, if the attendant originates a toll call, she will be signaled on a ringback from the toll operator.

Calls originated at PBX stations that are directed to unassigned numbers at the PBX are automatically routed to the PBX attendant.

Night service is now available by either of two methods. One method provides a key telephone set, shown in Fig. 3, for the person who serves as the night attendant. The other method connects certain central office trunks to certain PBX extension lines so that calls on these lines can be originated and received as if they were individual lines to the central office. This latter method is used when no attendant is on duty.

PBX Attendant Service Features

Significant new service features for the PBX attendants are provided in connection with the console shown in Fig. 2 and the key telephone set shown in Fig. 3. These features were designed so that the number of push buttons and lamps would be the minimum for the service requirements, and the size of the attendant's equipment would be the smallest practicable for easy operating.

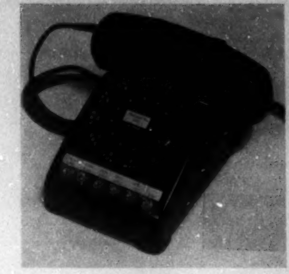

Fig. 3. Key telephone set for PBX attendant

In the attendant's console, each trunk appears on two lamps and a single push-button called a PICK UP button. Two other buttons are provided for use in connection with all of the PICK UP buttons. One is called the RELEASE button. The other is called the HOLD button.

In a fully equipped PBX, 18 PICK UP buttons are provided in the console for the main PBX attendant. Ten are connected to central office trunks and three to attendants trunks. The other five are available for miscellaneous purposes such as to pick up certain PBX lines so that the attendant can answer calls to these lines when the regular users are away. More than one attendant position can be provided for a single PBX to enable the active attendant to be at different locations at different times. An attendant's console may be equipped with only 12 PICK UP buttons instead of 18 where 12 are adequate for the service requirements.

All PICK UP buttons and the RELEASE button are of the 2-position locking type and are mechanically interlocked so that the pressing of any one will release any of the others that were previously operated. These buttons function like those of the familiar 6-button key telephone sets shown in Fig. 3. The RELEASE button is pressed by the attendant when she wishes to disconnect from a trunk without connecting to another trunk. If she does wish to connect to another trunk, she merely depresses the PICK UP button of this other trunk.

When the HOLD button is operated momentarily, it produces two results simultaneously: It places a HOLD condition on the central office trunk, and it connects the attendant to a register circuit with

VoL.
Pt. 1
195

dial tone so that she can dial the 2-digit number of the PBX station line desired by the outside calling party. The HOLD button is not mechanically interlocked with the PICK UP buttons.

The HOLD button is also used to release a connection through the PBX switches on infrequent occasions such as when the attendant makes a mistake in dialing and must release the connection and start over; when the called line is busy and the calling party does not wait, and so it is necessary to release the camp-on condition; and when a call from a trunk to a PBX line is transferred to another PBX line, and it is necessary to release the connection to the first line. This releasing function of the HOLD button is accomplished by successive operations. The first operation of the HOLD button causes a connection, the second operation causes a disconnect, the third another connection, the fourth a disconnect, etc. The attendant knows whether the connect or disconnect conditions exist by the visual signals from the lamps and the tone signal heard in her telephone set. The use of this single button to hold and also release is an important element of the design to enable the provision of small, compact, and simple pushbuttons and lamps for the PBX attendant.

The two lamps associated with each central office trunk provide distinctive meaningful signals. One of these lamps indicates the signals related to the central office side of the connection between the central office trunk and the PBX station line. The other lamp indicates the signals related to the PBX station side of the connection. Thus, these two lamps are comparable with the front and back supervisory lamps of a cord circuit in a cord-type switchboard.

Five different signals can be provided by each of these lamps: (1) dark, (2) steadily lighted, (3) flashing once every 2 seconds, (4) flashing once every one second, and (5) flashing twice a second. The slowest of these three flashes is called a wink signal because the flash consists of a very short dark period and a relatively long lighted period. A steadily dark lamp indicates that the circuit is idle. A steadily lighted lamp indicates that the circuit is busy. A flashing lamp indicates a call in progress. The speed of the flash is in direct proportion to the urgency of the action required of the PBX attendant. A flash at the highest speed (twice per second) indicates that the attendant should take action promptly. This occurs on an unanswered incoming call from the central office, on an unanswered recall after the completion of a call to a PBX station, and on a call to a busy line when another call is camped on the line. A flash at the intermediate speed (once per second) indicates that the called PBX station line is busy and that the trunk is in the camp-on condition waiting for the line to become free. The slowest flash (a wink once every 2 seconds) indicates either one of two different conditions: When this wink is on the trunk lamp, it indicates a HOLD condition on the trunk; when the wink is on the station lamp, it indicates that a connection has been completed through the switches to the station line and that the station bell is ringing awaiting the answer of the called party.

A "split" connection which enables the attendant to announce a call to a PBX station without the outside party listening in is automatically established when the attendent first completes the call. The "split" is automatically eliminated when the attendant disconnects. If she subsequently returns, the elimination of the split is continued, and she is then bridged on the connection; except that, if desired by the customer, the circuits can be wired to produce the split on all occasions while the attendant is connected so as to assure that the attendant cannot listen on conversations between PBX stations and outside parties.

Where the 6-button key telephone set, shown in Fig. 3, is provided for a PBX attendant, the method of operation is substantially the same as that described for the attendant's console of Fig. 2 except that only one lamp instead of two lamps is provided with each PICK UP button, and a switchhook button is provided instead of a RELEASE button. With only a single lamp, the attendant does not know whether the condition producing a flashing lamp is on the trunk side or PBX station side of the connection. However, this absence of a distinctive

indication of the source of the call is not serious where the amount of traffic is small.

Switching Apparatus

Most of the switching apparatus consists of relays of the wire spring type[1] and crossbar switches. A close view of this apparatus is shown in Fig. 4. These relays and switches are substantially the same as those in the latest types of crossbar central offices. The contacts on this apparatus that open and close the electric circuits are of the twin type that minimize troubles from dirt.

Each of the crossbar switches in this PBX has ten hold magnets, ten select magnets, six pairs of make contacts at most of the crosspoints, and two pairs of break contacts on each of the hold magnets.

Some of the wire spring relays are of the new "dual armature" type that provides two independent relays, each with as many as five sets of springs, in the same space required for a single relay with 12 sets of springs.

Equipment and Wiring Features

The external appearance of the cabinet housing the switching equipment is shown in Fig. 1. Fig. 5 is a view of the equipment cabinet with two of the sliding racks pulled out to the position providing access to the switching apparatus for maintenance purposes. The crossbar switches and wire spring relays are similar to those in no. *5* crossbar central offices.[2] Most of the wires to the terminals of this apparatus are attached by solderless wrapped connections like those also used in the latest types of central offices.

The structural framework holding these apparatus slides was carefully designed and tested to produce adequate strength with a minimum amount of material. Tests indicated that this framework will withstand a force of 2 tons applied from one corner to the furthest opposite corner. The apparatus racks are of aluminum to keep the total weight to a minimum. These racks are mounted on ball bearing slides so that they can be readily pulled out and pushed in. An interlocking mechanism among the three slides on each module prevents more than one of the three slides from being pulled out at any one time. This is a safety feature to avoid tipping of the cabinet that might otherwise occur if two slides were pulled out simultaneously. It also eliminates the necessity for fastening the cabinet to the floor.

The slides and modules are interconnected by a cable terminated in multicontact plugs located in the top of the cabinet as shown in Fig. 6. Access to these cables is provided by lifting the covers. The wires to the outside are also connected through plugs and jacks in the top of the cabinet.

The wires from the movable apparatus racks to the fixed plugs in the top of the cabinet are in a looped cable form held together by a canvas cover with a zipper fastener.

Power Supply

The power supply for this PBX is basically 48 volts d-c, capable of supplying 7.5 amperes continuously with momentary peaks up to 12 amperes. Most installations are furnished without batteries. However, electrolytic capacitors of 30,000 microfarads are provided to store power for a fraction of a second so that connections through operated relays and switches will not release during momentary failures or large voltage dips in the power supply. The batteryless type of power plant is located on slide 1 of the switching cabinet as shown in Fig. 7. In locations such as police and fire departments and hospitals, where continuous service is essential even during power failures of more than a fraction of a second, a battery can be added to the power plant and located in an adjacent cabinet.

In the batteryless type of power plant the 20-cycle voltages for ringing bells and the tones for busy and audible ringing signals are produced by saturable-reactor circuits driven by 60 cycles a-c. These are interrupted by cams driven by a 60-cycle a-c motor.

Fig. 9. Method of deriving 16 links from ten horizontal paths through the crossbar switches

In the battery type of power plant, transistor oscillator circuits are provided for generating the alternating voltages that produce ringing and tones and drive the motor of the interrupter. These transistor circuits operate entirely from the direct current supplied from the battery so that normal service will not be affected by a prolonged failure in the source of 60-cycle power. To safeguard service in case of failure of a transistor, two transistor circuits are provided for 60 cycles to drive the motor of the interrupter, and two other transistor circuits are provided for the 20-cycle ringing. One circuit of each of these two pairs is normally in service; but in case of failure, the other is automatically transferred into service, and an alarm is indicated. Only a single transistor circuit is provided for dial tone and busy tone because failure in these tones is not as serious as a failure in ringing.

Switching Plan

The switching plan uses nine crossbar switches in a fully equipped PBX, arranged as indicated in Fig. 8. The lines, trunks, junctors, and registers are connected to the verticals. The links are connected to the horizontals. Each of the nine switches has ten verticals. There is a total of 90 verticals accessible to all of the links on the horizontals.

These switches are wired so that 16 links are derived from the ten horizontals. This is accomplished by dividing the horizontals into two groups with eight in the upper group and two in the lower group, as shown in Fig. 9. On each of the eight horizontals in the upper group, there are two links. This provides a total of 16 links. One of these 16 links is selected by choosing one of the eight upper horizontals in combination with one of the two lower horizontals.

Each of the links has three wires. These are connected to a vertical by the closure of contacts at the point where the horizontal crosses the vertical. As there are two links on every horizontal, and three wires per link, there are six wires per horizontal and six contacts per crosspoint on each of the eight upper levels. Only three of the six wires are connected to crosspoint contacts on the first level, and the other three of the six wires are connected to crosspoint contacts on the second level. The connection from a circuit on a vertical to a link on a horizontal is completed through a crosspoint closed on the first or second level in tandem with another crosspoint on the same vertical closed through a crosspoint on one of the upper eight levels.

For each of the ten horizontals there is one select magnet on each of the nine switches. For each of the 90 verticals, there is one hold magnet. These magnets control the connections through the crosspoint contacts between the vertical and horizontals. To complete one of these connections, such as from a line to a link, the marker performs the following four steps in succession:

1. Connects to all the select magnets on the switch containing the vertical to be operated.
2. Operates the two select magnets that identify the link, one on one of the lower two horizontals, the other on one of the upper eight horizontals.
3. Operates the hold magnet.
4. Disconnects from all the magnets.

After the marker disconnects, the select magnets release, but the hold magnet is held operated via the crosspoints and the link.

Basic Circuit Operations

When a customer at a PBX station lifts the handset to originate a call, a line relay operates and summons the marker, as illustrated in Fig. 10. This causes the connections to be completed from the station line via an idle link to a dial pulse register from which dial tone is supplied to the station. When the customer dials the desired number, the dial pulse register circuit receives the dial pulses, translates them into the routing desired, and directs the marker to complete the connection through the crossbar switches to the desired point. Then the register circuit is released.

On a connection from one PBX station line to another station on the same PBX, the connection is completed via two links and one junctor as marked by the X's in Fig. 10. Six junctors are provided. They supply talking, supervisory, and

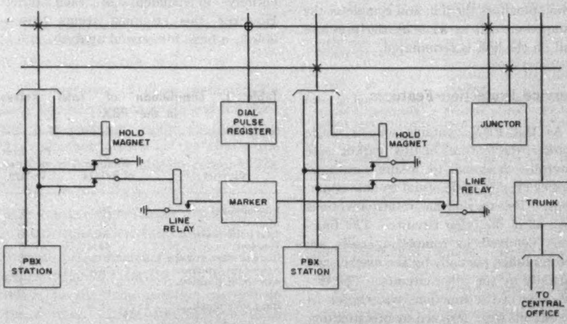

Fig. 10. Basic circuit operation of 756A PBX

ringing currents to the stations. Each junctor is connected to two verticals. One vertical serves the calling line and the other the called line.

On a connection between a central office trunk and a station line, only one link is used. When an incoming call occurs on a trunk, the call is answered by the attendant connecting directly to the trunk through contacts of a relay operated from the pick-up key of the trunk. The attendant completes the call by operating the HOLD button momentarily to cause a connection from her telephone set via the trunk and a link to a dial pulse register. After the attendant has dialed the number of the called station line, the connection is completed via the same link to the line and the dial pulse register is released. Then the ringing current to the station bell is supplied from the trunk circuit.

If the line is found busy when it is called from a trunk, the camp-on condition is produced in the trunk circuit as a result of certain tests made by the marker. The circuits for the camp-on condition make use of three different voltages that may be found on the sleeve lead of each link under different conditions. The first of these is −48 volts that is placed on every idle link by the marker during link testing. The second is −5 volts that is normally on every busy link. The third is 0 volts that is derived from direct ground connected by the marker to the sleeve of a line circuit after the line has been found busy. This direct ground on the line sleeve appears also on the link sleeve to which it is connected. The link test circuit in the marker searches for this direct ground to locate the link associated with the busy line from among the other links that have either −5 volts or −48 volts. The marker then connects the calling trunk to the proper link and establishes the camp-on condition in the trunk. A diode sensing circuit in the trunk monitors the link and completes the camped-on call as soon as the previous call on the link is terminated.

Service Protection Features

As this PBX contains only a single marker, the features of this marker were carefully designed to assure continual service in spite of the usual trouble conditions. This marker has interconnections with all of the other circuits. The functions involved in completing calls are accomplished partially by the marker and partially by the other circuits. The distribution of the functions was chosen as the circuits were designed by investigating various possible plans and then choosing the particular plan which produced the optimum combination of cost and reliability. The plan chosen was not the cheapest nor the most reliable but was judged to be the least expensive plan that would yield reliable operation.

The criterion of reliability used for this common control design was: "A single trouble of any one of the usual types experienced with relays, such as dirty contacts, crosses, grounds, open circuits, or faulty adjustments, shall not cause the failure of service on more than ten station lines, nor on more than one half of all links, nor on more than one half of all trunks in any one group."

To meet this criterion of reliability, the number of relays in the marker, the number of contacts on many of the relays, and the number of wires between relays is greater than that which would be required to provide the same traffic operating features if reliable service under trouble conditions were disregarded.

The extra cost of making the *756A* PBX reliable, above the minimum cost for merely operating under the most favorable conditions, is about 10 per cent of the total cost.

The relays in the *756A* PBX constitute the major portion of its cost. There are 731 relays in a basic *756A* PBX for 60 lines. These relays are distributed among the various circuits as shown in Table I.

FEATURES OF CENTRAL OFFICE TRUNK

Many of the service features derived from the central office trunks are produced by relays individual to the trunks. Other features are produced by relays in the marker and position circuits that are used on a common control basis for different calls on all of the trunks.

The features produced by the relays in these trunks are illustrated by Table II. These eight groups of functions are not entirely independent of each other. However, this grouping seems reasonable as a basis for general analysis.

MARKER ELEMENTS THAT ASSURE RELIABILITY

The principal elements of the marker that assure reliability are 75 pairs of relays called the "assurance pairs." These are arranged so that either one of each pair can alone continue the operation of the PBX if its mate fails. Other elements in this category are relays that cause second trials if failures occur on first trials, and various extra contacts on certain relays that are needed only when troubles occur.

MARKER ELEMENTS THAT FACILITATE LOCATION OF TROUBLES

To facilitate location of troubles, the marker contains 24 relays, 4 message registers, 12 lamps, and some miscellaneous contacts on certain other relays. These contacts interconnect with these relays and lamps so that an alarm is indicated if a trouble occurs. The different lamps help to locate the source of the trouble.

MARKER RELAY PAIRS THAT ASSURE RELIABILITY

If one relay of the 75 assurance pairs should fail to operate when its mate operates, an alarm is produced while service from the customer's viewpoint is continued without interruption. This method of duplicating relays serves in the *756A* PBX as the counterpart of two or more markers in the larger common control switching systems. In these larger systems, when a trouble in a relay blocks the progress of the marker, the block continues for a short time interval and then the other marker is automatically brought into service to complete the connection. In the *756A* PBX when a trouble occurs in one of these 75 pairs of relays, the marker continues to complete the call without delay and only an alarm condition is produced. Theoretically, it would be possible for several different troubles to occur simultaneously at

Table I. Distribution of Total Relays in the PBX

Circuits	Number of Relays	Per Cent of Total Relays
Line circuits	70	10
Marker	329	45
Dial pulse registers	58	8
Junctors	24	3
Central office trunks	210	28
Attendant trunks	24	3
Attendant position	4	1
Alarms	11	2
Busy tone trunk	1	–
Total	731	100

Table II. Functions of Relays in Central Office Trunk Circuit

Function	Number of Relays
Ringing from central office	2
Control signals to and from central office including delayed through supervision	5
Connector for leads to attendant's position	2
Holding central office, inward completing, and releasing	5
Machine ringing	2
Camp-on	3
Flashing recall	1
Toll diverting	1
Total	21

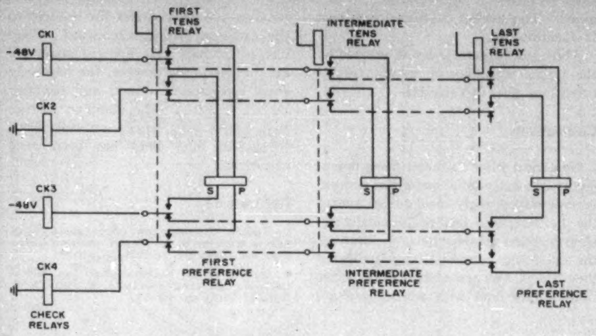

Fig. 11. Protective features of the tens and preference circuits of the marker

several points without interrupting service from the customer's viewpoint. However, the basic design objective has been to assure service only if one trouble occurs at a time.

The reaction on customers' service that could result if the functions of these 75 pairs of relays were performed instead by only 75 individual relays can be estimated approximately by considering the troubles experienced on similar relays in crossbar central offices. These troubles average about 0.5 per 100 relays per year. The actual number of troubles is influenced by the number of operations and the environment. However, this figure seems reasonable for the general analysis here.

The omission of these 75 relays from the marker would have left the marker vulnerable to a service failure any time a trouble occurred on any one of the remaining 75 relays. Thus, on the basis of an expectancy of 0.5 troubles per 100 relays per year, there would be an expectancy of a service failure of $0.5 \times 75 \div 100 = 0.375$ failures per PBX per year, or a failure of every PBX about once every 3 years. Each of these failures could destroy all service through the PBX for a considerable time until a repairman reached the PBX on the customer's premises and found the trouble. Such a frequent occurrence of complete failures would be substantially below the standard of reasonably good service from the customer's viewpoint. Therefore, these extra relays are provided in the standard product.

Extra Marker Contacts That Assure Release of Certain Relays

Other elements of the marker that assure reliability are a considerable number of extra contacts on certain relays that are arranged so that the release of certain other relays is caused by opening the circuits to both sides of a winding, one side going to ground, the other side to battery. For simple control disregarding trouble, it would be necessary to open the circuit on only one side of the winding. This principle of duplicating contacts assures the release of the relays even though one of the contacts be accidentally short-circuited. This is important in certain situations such as where the relays connect leads from individual trunks to the common control circuits and, if such relays should be accidentally operated, they would cause serious interference with normal service on many trunks.

Extra Marker Contacts That Assure Operation of Chain Circuits

Other elements of the marker which assure reliability are extra contacts on relays in the three principal chain circuits:

1. The tens selection chain.
2. The units selection and line and trunk hunting chain.
3. The link selection chain.

The first two of these chain circuits have two selecting channels and the third has four entrance points, so that, if a dirty contact occurs in the chain, the marker will still be able to complete the call.

Marker Lockout Relays That Assure Rotational Serving of Calls

Some other elements of the marker to assure reliability are the TA- and TRA-relays in the tens selection portion of the marker. There are eight of these relays for 60 lines, and six for 40 lines. They assure rotational selection of all calls waiting to be served by the marker even though a trouble in any one line or trunk circuit produces a condition that continually calls for the marker and tends to monopolize its use. These TA- and TRA-relays are important to reliability because if they were omitted, a failure on any one of the relatively larger number of line and trunk circuits could block service to nearly all other lines or trunks in the PBX.

Tens and Preference Circuits of the Marker

The tens and preference circuits in the marker control the sequence in which calls are served when several are simultaneously directed to the marker. The calls are handled via the tens group identifying circuit and the tens group preference chain that are illustrated in Fig. 11 in simplified form. These circuits have significant safety features because, if they were otherwise, a trouble in them could disable the PBX.

When a call is waiting to be served by the marker, one of the tens relays is operated.

To guard against the more common types of trouble such as open circuits or leads crossed to ground or battery, two separate windings are furnished on each preference relay. Both of these windings are normally open at contacts of the corresponding tens relay. The other contacts on the tens relays are wired in a series

Table III. Typical Relay Troubles and Remedial Action

Kind of Trouble	Circuit Action
Primary winding of a preference relay becomes open	Check relays *CK1* and *CK4* fail to operate, producing alarm. Preference relay operates on its other winding
Primary winding of a preference relay is falsely grounded	*CK4* will be short-circuited and will not operate. This produces an alarm, but the preference relay operates on its other winding
False ground on an upper normally closed contact of a tens relay	*CK1* operates at once to produce alarm. Preference relay will operate on other winding
False ground on a lower contact of a tens relay	*CK2* does not operate when *CK4* operates and this produces alarm. Preference relay operates on both windings
Tens relay fails to operate	Lines associated with that tens group cannot make outgoing calls. Other groups are not affected
First or intermediate tens relay operates falsely	A timing relay (not shown) operates after a short interval to force the release of this tens relay. Other tens relays can then operate their preference relays

chain arrangement so that only one preference relay will operate at a time even though more than one tens relay operates. The check relays *CK1* and *CK4* operate in series with one winding of the preference relay involved on each call. The check relays *CK2* and *CK3* operate in series with the other winding of the same preference relay. All four check relays operate in series with a preference relay each time a call is made. That is an indication that all is well. If one or more check relays operate and at the same time one or more other check relays of the four do not operate, either before a call starts or during progress of a call, an alarm is given. The marker, however, continues to function.

These safety features are illustrated by the typical examples of specific trouble conditions given in Table III.

Conclusions

New *756A* PBX's are now being manufactured in substantial quantities and will become increasingly prominent among the dial telephone facilities at moderate-sized business establishments. Many of the operating personnel have indicated they believe this new system to be better than former ones with which they are familiar and they prefer the console to the former cord-type switchboard. They like particularly the modern, attractive appearance of the console, the relatively small equipment cabinet, and the new service features. The camp-on feature that comes into service on calls from trunks to busy lines has been very attractive.

Assessment of Effects of Delay Distortion in Data Systems

A. D. FOWLER
NONMEMBER AIEE

R. A. GIBBY
NONMEMBER AIEE

AN ESSENTIAL objective of a pulse transmission system is the preservation of some aspect of the pulse shape at the receiver. The phase characteristics of a system, which can generally be neglected in voice transmission, become important in pulse systems, since the shape of a pulse is influenced greatly by the phase of the energy components of the pulse spectrum. A quantity frequently used in describing this influence is the "group delay" or "envelope delay." It is a measure of the relative phase shift experienced by neighboring components of the frequency spectrum and is equal to the slope of the tangent to the phase curve at any given frequency. If the phase shift changes linearly with frequency, the envelope delay is constant across the band, and there is no delay distortion. When the envelope delay varies with frequency, however, the shape of a pulse is degraded or distorted in transmission. This variational component of envelope delay will be called the delay distortion.

When the delay distortion of a transmission system becomes large beyond a certain maximum value in the energy band of a pulse signal, the performance of the system becomes unsatisfactory. For smaller values of distortion, satisfactory performance may be possible but the signal is transmitted with a reduced margin against failure due to noise.

In practice many different delay distortion characteristics are encountered in transmission lines, depending on the type and length of line, number of repeaters, etc. It would be an almost impossible task to take all of these characteristics into account unless some organized approach were used. It would be helpful if the degradation produced by delay distortion could be considered in the same way as degradation due to noise. This approach is complicated, however, by the fact that delay distortion cannot be represented as a single number (such as rms power of a given noise spectrum), but varies across a band of frequencies.

It can be shown that for voice-frequency transmission circuits, many delay distortion curves have the common property of approximate parabolic shape about a vertical axis. Since a parabola is defined by three points, it is possible to represent the delay distortion approximately by the values of delay at three frequencies. These three frequencies are also useful in defining two parameters which can be used to designate a given parabolic delay characteristic. The manner of defining these two quantities is shown in Fig. 1. One parameter is the slope, M, of a straight line intersecting the parabola at the lower frequency f_1 and the upper frequency f_3. The other is the sag, S, which is the distance at mid-frequency, f_2, between the parabolic curve and the straight line defined in the

Fig. 3 (above). Slope-sag plot of message facilities and 26 type equalizers

reference to slope. Any parabola having symmetry about a vertical axis can be designated by the two parameters M and S, as illustrated in Fig. 1.

Using the three frequencies $f_1=1{,}200$, $f_2=1{,}800$, and $f_3=2{,}400$ cps (cycles per second), the delay distortion curves for many voice-band facilities can be represented by parabolas with discrepancies no longer than about 50 μsec (microseconds) over a range from 1,000 to 2,600 cps. This accuracy is within the capabilities of most existing delay-measuring equipment covering this frequency range. The parabolic approximations of delay for four message circuits are compared with the actual delay distortion characteristics in Fig. 2.

The slope and sag of a parabola do not depend on the absolute delay, and will not be altered if an arbitrary value of delay is used as reference. If the delay at frequency f_2 is chosen as reference, the quantities M and S can then be defined in terms of the delay values as

$$M=T_3-T_1$$

$$S=\tfrac{1}{2}(T_3+T_1)$$

where T_1 and T_3 are the delay at f_1 and f_3 respectively, and T_2 the delay at f_2 is given a value of zero.

This method of representing a delay characteristic has a number of advantages. By this representation a given delay may be specified by only two numbers. When a variety of transmission facilities are considered, the quantities M and S will take on a range of values. They may be considered as forming the co-ordinate axes of a plane, on which any facility can be represented as a point. This method of designating transmission circuits can also be applied to delay equalizers which frequently have parabolic characteristics also. In Fig. 3 a number of message facilities and equalizers are located as points on the slope-sag plane. It is usually the case that message circuits are located in the upper half of the plane (positive sag) and equalizers in the lower half (negative sag).

A useful property of the parabolic characteristics is that, if a number of parabolas are added point by point, the sum is also a parabola. In addition, if the slopes of individual parabolas are added, and the sags of individual parabolas are added, the sums are equal respectively to the slope and sag of a parabola resulting from a point-by-point addition of the individual parabolas. Thus, if a given message circuit, designated by a point on the slope-sag diagram, is doubled in length, the resultant delay curve will be a parabola having twice the slope and sag of the original circuit. (For carrier and other facilities where the terminals contribute a large part of the delay distortion, doubling the "length" of the circuit must be construed to include doubling the number of terminals as well.) The point representing the second case would be located on the M-S plane, on the same radial line as the point for the first case, and at twice the distance from the center. Also, if two circuits are connected in tandem, one having values of M and S equal in magnitude and opposite in sign to the respective values of M and S of the other, the result will be cancellation of delay, or equalization. This additive property of the slope and sag quantities makes the task of equalization a rapid and convenient one, since equalization requirements can be prescribed and equalizers can be selected and combined with ease.

This paper gives the results of tests

Fig. 6. Illustration of failure conditions on slope-sag diagram

in which the delay distortion characteristics of transmission systems were considered on a slope-sag basis, and performance of a data system was evaluated in terms of slope and sag. These results provide a means of determining the performance of any facility or combination of facilities having parabolic delay distortion curves when used in connection with a particular data system. Also, the suggestion is made that these results could be expressed on a generalized basis, and may be extended to data systems having a different frequency range, or different bit rates.

Method of Testing

In order to investigate performance on the basis described, tests were made on a data system as shown in Fig. 4. For this system the signal source was a random binary data signal. The individual data pulses have a raised cosine shape. The system operated at a rate of 1,650 bits per second. The data signal was amplitude-modulated on a 2,200-cycle carrier, and was transmitted with a vestigial upper side band.

The performance of the data system was found to be closely related to the average rate of transitions from one state to another in the pulse train. For a binary signal which has a random occurrence of "on" and "off" pulses, the average number of transitions is equal to one half the bit rate. (There is equal probability that the signal will remain in a given state or undergo a transition from one state to another in one sampling interval.) If the signal source is biased in such a way that the number of short sequences of "on" and "off" pulses is reduced, and the number of long sequences is increased, the average transition rate is reduced. For a given signal-to-noise ratio it was found that this type of bias reduced the number of errors or enhanced the performance. If the signal is biased in the opposite manner (more short sequences, the fewer long sequences), the system performance was degraded. For all the tests described in the following discussion, the average rate of transitions was held at one half the bit rate.

The over-all amplitude characteristics of the system including vestigial filtering are shown in Fig. 5. These characteristics were designed with considerable care, in order that the transient response due to amplitude distortion would be minimized. The amplitude characteristics were not changed throughout the test. The over-all delay characteristics with the system connected back-to-back were equalized, except for a small nonparabolic residue which could not be conveniently eliminated.

The objective of the experimental tests was to determine how the data system would perform with a wide variety of different delay-frequency characteristics. A variety of delay curves was obtained by the use of the variable delay network indicated in Fig. 4. It was necessary to use a specially designed network rather than actual transmission facilities, in order to provide control over the shape of the curves, and over the noise applied to the system. With this network, adjustments of delay could be made so that any value of slope or sag of interest to the test could be prescribed.

Thermal noise was introduced into the system through a low-pass filter (having a cutoff at 3,000 cycles), an attenuator, and a mixing pad. The output of the pulse receiver was compared with the transmitter output by the error checker which registered a count whenever a pulse polarity at the receiver differed from what it was at the transmitter. If the number of errors exceeded the error criterion (five errors per minute in this case), the system was considered as "failing"; otherwise it was considered to be "working." Under conditions of no delay distortions, the data system operates at the point $M=0$, $S=0$. The signal-to-noise ratio for this point is the smallest ratio for any point on the slope-sag plane, and for ideal terminals it is equal to the theoretical limit of transmission. This is shown in Fig. 6, as the point for failure due to noise alone.

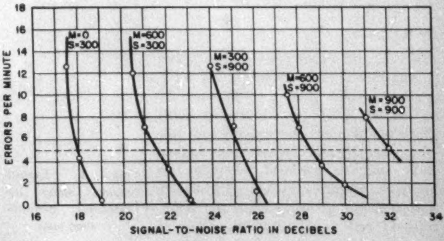

Fig. 7. Error rate curves for various slope-sag values

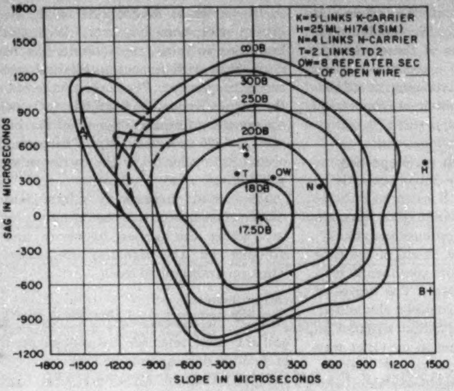

Fig. 8. Slope-sag diagram for vestigial-side-band system, 1,650 bits per second

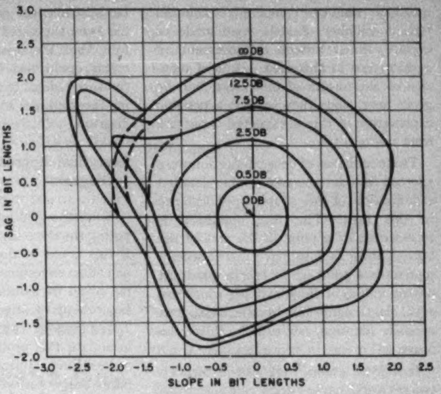

Fig. 9. Normalized slope-sag diagram for vestigial-side-band system

Now consider conditions of no noise, with the slope held at zero. As the sag is increased, a point is found for which the system will fail due to sag alone. Also for conditions of no noise and with the sag held at zero, let the slope increase. There is then a point at which the system will fail due to slope alone. These two points are also shown on Fig. 6. There are many combinations of slope and sag represented by points on the plane, which will also result in failure with the noise removed. If these points are connected, a contour of failure due to distortion alone will result. This is known as the infinite decibel signal-to-noise ratio contour. This contour is shown in the first quadrant in Fig. 6. It may be extended to the other three quadrants as well.

For a point on the *M-S* plane outside of the infinite decibel contour, the data system fails regardless of the noise conditions; therefore, these points were not tested. For points inside this contour the system works with a margin against failure when no noise is present. The margin is determined by the amount of noise which must be added to produce failure.

With the variable delay network set to give a particular slope and sag, the noise was adjusted to a certain level, and the performance in terms of the number of errors was observed for a 5-minute period. By adjusting the noise level to other values and repeating this procedure, a curve of the error rate versus the signal-to-noise ratio was obtained. In Fig. 7 curves of this type are given for five points located in the first quadrant of the slope-sag diagram. The intersection of any of the curves with the dashed line which designates the error criterion determines the signal-to-noise ratio which represents failing conditions for that particular point. Failure in each case is due to the combined effects of noise and delay distortion.

Additional measurements of this type were made for other points ranging over the entire slope-sag plane. A signal-to-noise value was then assigned to each point tested. Many points were found to have very nearly the same margin against failure, and contours of equal signal-to-noise levels were plotted by interpolation. These contours make up what is referred to as the slope-sag diagram shown in Fig. 8.

Results

Several features of the slope-sag diagram should be considered in detail. First it should be noted that the contours of this diagram are related to the characteristics of a particular data system, and to the error criterion used to define a condition of satisfactory performance for that system. If another criterion were used, a second set of contours could also be determined. For a more rigid criterion, the contours will in effect move inward on the diagram, while for a more lenient criterion the contours will move outward.

Also, it is significant to note that in the center of the diagram, the contour lines are spaced relatively far apart. This indicates that when delay distortion is small (slope or sag less than 600 μsec), any change in delay has only a small influence on performance. This means that little is gained by delay distortion correction in this region. With the exception of the *H174* loaded cable, all of the transmission facilities indicated in Fig. 8, fall within 600 μsec of the origin. The contours indicate that these facilities will perform satisfactorily with a signal-to-noise ratio as low as 20 decibels. In the region of relatively large delay distortion (slope or sag greater than 600 μsec), however, the influence of delay distortion becomes more critical, and equalization is more desirable, and even imperative.

The amount and type of equalization necessary to improve a given transmission facility or combination of facilities by a certain amount can now be determined directly from the slope-sag diagram. It is sometimes necessary to establish a compromise type of equalization which will not give complete correction for any one facility, but will allow a number of facilities to operate with the same amount of degradation, or within the same contour on the slope-sag diagram. Equalization of this type can be performed by equalizing for the average position of all the facilities under consideration.

The contours on the slope-sag diagram appear to be circular in shape in the regions of lower distortion. So far this shape has not been confirmed by theoretical analysis. The rather large bulge in the outer contours in the second quadrant cannot be completely accounted for. A number of tests were made to explore the apparent enhancement of performance in this area. A brief mention of the results of these tests will be given here, since they suggest a possible explanation of this unexpected departure from uniformity.

Two conditions of delay distortion were selected in order to make a more detailed examination of the system performance in this area. The first condition is represented by a point in the area of the bulge, shown as A in Fig. 8. The second represents a point in the fourth quadrant having values of slope and sag which are equal in magnitude to the first, but opposite in sign, shown as B in the figure.

Individual pulses were passed through two networks having delay characteristics described by the conditions referred to in the foregoing, and the output pulses were compared. It was found that the transient oscillations in the case of the first network were smaller than those for the second network indicating a confirmation of the reduced degradation in the region of the bulge.

These tests were repeated for two other data systems of the same general type. (One was a system which produced a data signal similar to that described previously. The other was a system having a 2,000-cycle carrier frequency and operating at 1,600 bits per second but otherwise similar to the system tested.) For each of these systems the transient responses were very nearly the same for each network. It was concluded from this that the bulge in the contour pattern was produced by the particular data system used in determining the contour diagram. It was also established that the performance of the data system was very sensitive to minor variations in the delay characteristics when it was operating under conditions of large delay. These facts suggest that the enlargement in the contour pattern may have been due to the unequalized residual in the envelope delay of the data system. Positive confirmation of this explanation could not be made.

It has been shown by E. D. Sunde[1] that for two delay distortion curves, one being the exact negative of the other, the pulse response is reversed in time, but the amount of degradation to the pulse is unchanged. (Equations 2.10, 2.11, and 2.12 of the Sunde paper show that a reversal of sign of the phase characteristics and time leaves the envelope function of a pulse unchanged.) For this condition, the contours of Fig. 8 would be symmetrical about the origin. It has been suggested by Mr. Sunde, therefore, that the results of these measurements could best be compared to other measured data by averaging or adjusting the contours to obtain a symmetrical diagram.

Analytical Approach to Slope-Sag Diagram

Some thought has been given to computing the slope-sag contours analytically. If this could be done, much of the time and effort necessary for experimental testing could be eliminated. The degree of experimental testing could be eliminated. The degree of complication required to formulate this problem in an exact way makes this approach rather difficult, particularly for vestigial-side-band systems as used here. The method of describing the delay distortion curves by a parabola has certain disadvantages from the standpoint of mathematical analysis. This approach was used principally to investigate a wide variety of delay characteristics. As a basis for a computation of pulse distortion, it has not proved to be mathematically tractable. This disadvantage might be overcome by approximating the delay distortion by some other simple shape such as a portion of a sine wave, which could also be specified in terms of two parameters.

A set of slope-sag contours has been computed by P. Mertz by making certain simplifying assumptions. One of these involves a linear weighting of the importance of different portions of the energy spectrum in producing transmission impairment. A weighting was found which gave results somewhat in agreement with the contour determined experimentally, but the analysis indicated that a linear spectrum weighting did not adequately describe the actual conditions.

Application of Results to Other Systems

The foregoing experimental results give a rather complete description of the performance of a particular data system under any condition of parabolic delay distortion. If these results could be made available on a normalized basis, rather than for a specific data system, it is likely that they could be used to express the performance of other systems as well. As a first step in normalizing, these results will be considered to apply only to systems of the same general type as that tested (that is, amplitude-modulated, with a vestigial upper side band) and rule out such systems as double side band, frequency shift, homodyne, etc. With this limitation in mind, these results can be normalized with respect to bit rate and carrier frequency. For the system tested, the carrier frequency $f_c = 2{,}200$ cps, and the signaling frequency (one half the bit rate) $f_s = 825$ cps, which at line frequency occurs 825 cycles below the carrier or at 1,375 cps.

Normalized frequencies referred to carrier transmission may be expressed by subtracting the carrier frequency and dividing by the signaling frequency. Thus, on a normalized basis,

carrier frequency $= 0$
signaling frequency $= -1$ (lower side band)

and the three reference frequencies used in defining slope and sag become

$f_1 = -1.2$

$f_2 = -0.48$

$f_3 = +0.24$

This normalized frequency is shown superimposed on the regular frequency scale, in the transmission characteristics of Fig. 5.

In order to normalize these results, it is also necessary to express the delay, and the slope and sag, in terms of the bit length rather than directly in units of time. When this is done, the slope-sag diagram can be presented in a normalized form, as shown in Fig. 9. This diagram is still restricted to a given type of system with a given error criterion and to parabolic delay distortion. In addition, there are other restrictions on its generality such as a particular amplitude characteristic and method of timing recovery. Its application has been broadened considerably, however, since it can now be applied to many systems having different carrier frequencies and bit rates.

Conclusions

This method of mapping the performance of a data system has proved to be a valuable tool. It has provided an organized approach to a complex problem and results in a clear means of portraying many aspects of a data system in a systematic way. It has increased the general understanding of the effects that various kinds and amounts of delay distortion have on data system performance.

The results of these tests are valid only under conditions of parabolic delay distortion. Since actual delay conditions which depart from the parabola are encountered in practice, there is a need for extending this approach to include other, more complex delay characteristics.

There is a need at the present time for

the results of tests on many types of data systems to be accumulated and compared. This would allow a more complete evaluation of different data systems, and their performance over different transmission facilities. The method of portraying system performance given here could be used as a basis of this comparison.

These results have been generalized to some extent through normalization with respect to carrier frequency and signaling frequency. Through this means they may be used to give an estimation of the performance of other systems of the same general type. There is the possibility that the results may be extended to include additional types of systems as knowledge in this area increases.

The tests described here were time-consuming because of the complexity of adjustments required for determining performance at each point tested on the slope-sag plane. This work could be reduced considerably by the use of specially designed delay networks which could be quickly adjusted to give any required value of slope and sag. This approach to further testing is now being investigated.

Dial Telephone Service for Smith Island, an Isolated Community in Chesapeake Bay

M. E. LITTLETON
ASSOCIATE MEMBER AIEE

THE utilization of very-high-frequency (vhf) and ultrahigh-frequency (uhf) radio facilities to provide short-haul toll, rural subscriber, or other point-to-point communication systems has answered the demands for modern telephone facilities in small isolated locations. In October 1957, The Chesapeake and Potomac Telephone Company of Maryland combined two radio-carrier terminals and associated central office equipment to provide three communities on Smith Island, Md., as shown on Fig. 1, with the latest dial telephone service.

The present system replaces a unique vhf radiotelephone communication system developed by Bell Telephone Laboratories. This system was installed in 1941 and provided facilities to serve Smith Island and Tangier Island from Crisfield, Md., a distance of 10 and 13 miles, respectively. The principal portion of the radio path is over water and a small portion over marshes and lowlands resulting in line-of-sight transmission. Since the volume of telephone traffic was expected to be small, one radio channel was provided and was shared by both islands. The radio equipment consisted of 160-mc (megacycle) 15-watt amplitude-modulated transmitters and associated receivers located in Crisfield serving both locations on a shared basis. This installation made provisions for six telephones on each island. The Crisfield radio transmitter and receiver were mounted on 50-foot poles with wire extensions to the central office manual switchboard. Although the normal communication was between the islands and Crisfield, it was possible to communicate from island to island by passing through the Crisfield radio equipment and being retransmitted through a by-pass connection. Each subscriber's telephone was equipped with a key that enabled the subscriber to select either a local party line, which furnished intracommunity communications, or a radiotelephone line connecting to the radio terminal. Each subscriber's set had a bell which could be rung by the operator in Crisfield using a selective signaling system.

In 1942, a 9-station magneto private line was provided to interconnect the three communities on Smith Island but did not connect to the radio. While this service provided telephone facilities for the intra-island communication, it did not allow two of the three communities to have direct telephone contact with Crisfield and other mainland points.

In recent years, the demands placed on this service indicated that more adequate facilities were needed. A comparative study was made to determine the most practical method of providing modern telephone communications to span the 10 miles of water separating Crisfield and Smith Island. This study showed that a dial central office with trunks to Crisfield on a multiplexed radio system would be more economical than either a submarine subscriber cable or a dial central office with a submarine trunk cable. There also was the possibility that submarine cable might be damaged during dredging operations in the oyster beds located off the shores of Smith Island. A uhf radio system was selected rather than a microwave system due to the relatively small number of voice circuits required.

Two uhf radio systems now connect Smith Island with the Maryland mainland at Crisfield. Preliminary surveys of the 213 families and 18 business establishments on the island indicated that facilities which would provide a total of six communication channels for off-the-island communications should be sufficient to satisfy local demands for service.

The largest of the three island communities is Ewell and its location, on the northern end of the island, provided not only a favorable location for a central office but also an excellent antenna site. Rhodes Point connects to the new central office at Ewell over 1.5 miles of aerial cable facilities. The southernmost community is Tylerton which is separated from the island mainland by Tyler Creek, see Fig. 2, and is served by aerial cable and 300 feet of submarine cable.

Radio Equipment

Two Dumont *MCA 484B* broad-band radio terminals as shown in Fig. 3, operating in the 450-mc frequency range, provide the radio facilities. The base-band frequency response of 0.2 to 11.2 kc allows for the multiplexing of a voice-frequency channel, two single-side-band suppressed carrier channels together with three associated signaling channels. The broadbanding of this equipment, which had previously been available on a single-channel basis, was accomplished through

the mutual co-operation of the Dumont Laboratories and the Bell Telephone Laboratories. For continuous duplex operation, the operating frequencies of the transmitter and receiver are separated by 5 mc. Actual operating frequencies as well as transmitted levels are shown in Fig. 4.

Antennas

Each radio terminal utilizes four Andrew's hurricane-type corner reflectors mounted as shown in Fig. 5. The supporting poles are 65 feet high with a 30-foot separation between bases. Special footings were needed at both locations to prevent excessive settling of the antenna poles into the soft terrain while reinforced guying was provided as protection against the ever-impending bay storms. The transmitting and receiving antennas of each radio system are horizontally polarized and mounted on a common pole. They are spaced 10 feet apart to provide the required decoupling between the transmitting and receiving paths. The antenna poles of the two radio system are separated by 30 feet to provide isolation between the two radio systems.

Multiplex Equipment

Two Lenkurt type *33B1* telephone carrier systems, as shown in Fig. 6, provide a compact arrangement for the application of three telephone channels to broad-band radio communications facilities. Each carrier system will provide one voice frequency, two carrier-derived channels, and three signaling channels. The voice-frequency channels occupy a band of frequencies between 200 and 3,000 cycles per second. Two additional channels are carrier-derived and convert voice frequencies of 300 to 2,700 cycles per second to single-side-band suppressed-carrier amplitude-modulated transmission at higher frequencies. Channel 2 transmits and receives on the upper sideband of 3.5 kc and Channel 3 transmits and receives on the lower sideband of 11.5 kc, as shown in Fig. 7. The block diagram of three channels of the radio carrier system including compandors and voice-frequency terminating units are shown in Fig. 4. Signaling for dialing and supervision on the three channels is transmitted and received at carrier frequencies of 7.5, 7.0, and 8 kc for Channels 1, 2, and 3, respectively. Each channel utilizes a compandor unit[1] to provide an effective increase in signal-to-noise ratio. Two-wire facilities connect the Crisfield central office to the radio-carrier equipment located at the Crisfield terminal building.

Dial Central Office

The new office established on Smith Island is a Western Electric type *356A* step-by-step community dial central office with a capacity of 200 individual lines. The office is arranged for normal 2-letter 5-digit dialing and is identified as HAZEL-5. While local intra-island calling is made on the 2-letter 5-digit basis, incoming and outgoing calls to Crisfield and distant points must be routed through an intermediate operator in the Crisfield central office. Island subscribers may reach the Crisfield operator by dialing 0. With the advent of direct-distance dialing in this area, no major modifications to the Smith Island central office equipment will be required. Direct trunks will then be provided to the toll center located at Salisbury, Md., utilizing a combination of radio and land carrier systems. The

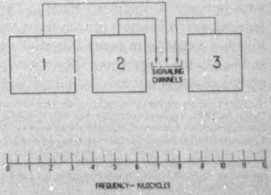

Fig. 7. Multiplex channel allocations

Smith Island–Crisfield trunks, described herein, will then provide for direct dial service between the two communities.

Alarms and Controls

The alarms and controls of this communications system appear as both audible and visual alarms on the Crisfield cental office switchboard with instructions to authorized personnel for their interpretation and operation.

The functions of the Crisfield radio and carrier equipment are transmitted over regular telephone cable facilities.

The remote indication and control of the Smith Island equipment is obtained by the integration of the built-in radio-carrier functions and the regular alarm system associated with the dial central-office equipment. In the event of an equipment failure on Smith Island, the appropriate alarm relay will seize an idle voice channel and will light a lamp associated with that trunk on the Crisfield switchboard. Upon receiving no response on this trunk, the operator will know that a trouble condition exists. The operator will then dial a predetermined level code into another Smith Island trunk to determine the nature of the alarm. "No tone" will constitute a major alarm, a "busy signal" indicates a minor alarm, while a satisfactory condition is indicated by two rings. Alarm indications include low transmitter power, low received sensitivity, emergency a-c power failure, and several types of central office equipment failures.

The Smith Island transmitters are controlled from Crisfield by dialing a level code into an idle radio trunk which when received in the island central office will turn the appropriate transmitter on or off.

Power

The basic power for the radio-carrier system is single-phase 115-volt a-c, 60-cycle. An interesting side note on the power for Smith Island is the fact that commercial power is generated on Tangier Island using the diesel-driven generator facilities of the Chesapeake Island Electric Cooperative. The power is then fed over 10 miles of high-voltage lines on poles located in the intervening marshes with high level crossings over navigable channels.

The emergency a-c power for the buildings on Smith Island and Crisfield is provided by Koehler diesel-driven automatically controlled alternators with a single-phase 60-cycle output of 10 kw at 230/115 volts a-c. In the event of a power failure the generator will start automatically after a 3-minute time delay and will continue to operate for 5 minutes after the initial restoration of power.

Conclusions

The use of two radio-carrier systems in conjunction with a dial central office has provided the isolated communities on Smith Island with a modern, reliable telephone service. The acceptance of this service by the islanders is evidenced by the fact that the number of telephones has increased from 120 to 140 in a 4-month period.

Public Air-Ground Telephone Service Trial

L. M. AUGUSTUS
NONMEMBER AIEE

WHILE radio communication to airplanes has been in everyday use for many years, until September 15, 1957, the only public telephone service available to aircraft has been that furnished through coast stations which have been established for the provision of telephone service to ships. Approximately 600 aircraft are registered for service through coast stations operating in the 2-mc (megacycle) frequency range. The service is not satisfactory in many respects. It is not available in many inland areas and due to the crowded conditions on the marine channels fast-moving aircraft are frequently unable to receive any service before landing at their destination. In addition, atmospheric noise at these frequencies seriously limits the range and reliability of the service. Even with these limitations the service has grown as shown in Fig. 1.

In order to obtain practical experience with the aircraft communications problem, two experiments have been conducted. At the time of the Provisional International Civil Aviation Organization meeting in Indianapolis, Ind., in October 1946 in co-operation with the Civil Aeronautics Authority (CAA), an airplane was equipped for operating with urban mobile stations in the 152–162-mc range. This installation was used experimentally during the meeting for communication through the Indianapolis urban mobile land station facilities which were, at the time, undergoing test. In addition to the experiments with the CAA airplane, a United Air Lines Douglas *DC-6* airplane was fitted with 152–162-mc land mobile equipment and experimental calls were made during the inaugural flight and certain other flights thereafter. The tests indicated that an aircraft flying at altitudes from 10 to 20,000 feet would cause interference with land mobile stations using the same channel within a radius of 200 miles or more. The experiments showed conclusively that a good grade of telephone service could be given to aircraft employing frequencies in the 150-mc

range but that channels separate from those employed for land mobile telephone service would have to be used.

The growth in the number of civil aircraft has been phenomenal since the end of World War II. According to current estimates a total of about 65,000 active civil aircraft are flying more than 13 million hours a year. Several aircraft-user groups have repeatedly expressed a growing interest in public air–ground radiotelephone service connecting to the land-telephone network. This was specifically expressed by the National Association of State Aviation Officials in a resolution adopted by the Board of Directors in Washington, D.C., on February 2, 1956, and submitted to the Federal Communications Commission (FCC). This resolution together with a request from the National Business Aircraft Association for a "Special Service Communications Channel" was subsequently considered by Special Committee *56* of the Radio Technical Commission for Aeronautics. Since that time several informal meetings have been attended by representatives of commercial airlines, military services, operators of executive and private aircraft, radio equipment manufacturers, and telephone companies. The interest expressed at these meetings indicates that there is a compelling need for air–ground telephone service connected with the land-line telephone network.

Early in 1956 a government–industry meeting was held in Washington under the chairmanship of C. A. Petry of Aeronautical Radio, Inc., to discuss "in-flight radiotelephone service to aircraft."

At subsequent meetings with representatives of manufacturing companies interested in building air-borne radio equipment, the U. S. Independent Telephone Association, Aeronautical Radio, Inc., and the Bell System, it was generally recognized that the telephone industry is in the best position to provide the ground facilities for public telephone service to airplanes. In order to obtain suitable frequency allocations to provide the numbers of channels such a service may need within a few years, it is necessary to develop plans for service on a nationwide basis.

Trial

As an aid in evaluating some of the questions encountered in developing such plans, a limited trial has been undertaken with ground stations at Detroit, Mich., and Chicago, Ill. The purpose of the trial is to provide needed technical data and traffic operating experience under actual flight conditions over a substantial part of an important route.

The frequencies used are 454.95 and 459.95 mc, normally assigned to the Domestic Public Land Mobile Service. These frequencies were chosen in order to obtain transmission information for frequencies well above those presently used for commercial operational air–ground communication. Theoretical consideration of path loss and antenna requirements lead to the conclusion that frequencies no higher than those in the lower part of the ultrahigh-frequency band will be feasible without appreciably restricting the range. These are also the highest frequencies for which commercial mobile equipment is readily available. Under a developmental grant the FCC has authorized the use of these frequencies at Chicago and Detroit for service to aircraft until September 1959. Fig. 2 is a view of the antenna installation on the Field Building in Chicago. Fig. 3 is a view of the Detroit antenna installation at Dixboro, Mich. The Detroit site is in relatively flat open country. The Chicago antenna installation is approximately 535 feet above the surrounding land while the Detroit antenna height is approximately 50 feet.

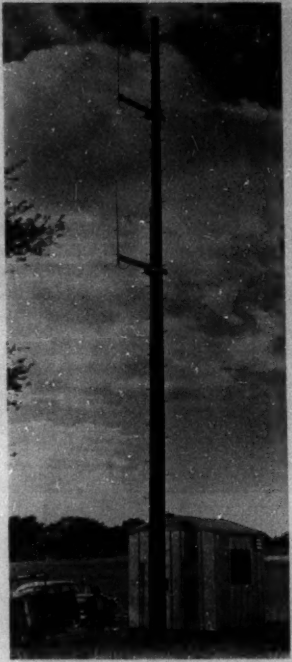

Fig. 3. Detroit transmitting and receiving station

Tests at these widely different sites should provide useful information for most of the base stations which would normally be encountered for a nationwide service. Frequency modulation was employed for these tests in view of its demonstrated advantages for a service to be used by the public. One of these advantages, the capture effect, appears to be of unusual significance in air–ground service where cochannel interference is a principal problem. The capture effect can be illustrated by analysis of a tape recording taken in a *DC-3* plane traveling 180 mph at an altitude of 8,000 feet on a direct route from Detroit to Chicago with transmitters at both these cities operating on the same frequency, modulated by different talkers. At the beginning, while the plane is in the area where the Detroit station is controlling, only the Detroit talker is heard. As the plane moves into the interference zone, a heterodyne appears, caused by the Chicago station. The impairment to the Detroit transmission is slight for a period of about a

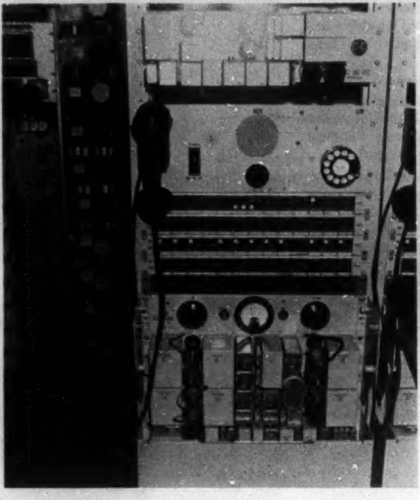

Fig. 4 (left). Western Electric G-2 control terminal

Fig. 5 (above). Switchboard positions at Detroit station

minute and a half, then rapidly becomes worse until the intelligence is completely lost due to the near-equality of the two received signals. The transition period lasts about a half-minute, before the Chicago talker is heard identifying the Chicago station, with the Detroit talker just apparent in the background.

With a ground speed of 180 mph, the half-minute transition represents $1^1/_2$ miles of flight. Other recordings taken at higher altitudes indicate a more extensive zone of interference as might be expected from the greater overlap as altitude is increased.

Since the coverage areas of the two stations overlap considerably at high altitudes, the operating practice will be such that the two stations will not transmit simultaneously if either is working an aircraft in the interference zone. By an arrangement including a co-ordinating circuit and monitoring facilities each operator will know when the other base station is handling traffic and whether the aircraft using the channel is in the overlap zone. Under these conditions, she will not energize the local transmitter.

Transmitting and Receiving Equipment

The equipment arrangements in the Detroit station used in this system were designed by the Bell Telephone Laboratories to incorporate the features which have been found to be desirable for common-carrier mobile radio services over the past 10 years. For example, a radio-frequency indicating device coupled at the transmitter output is used to provide an indication to the traffic operator that the transmitter is energized and she may dial the called party. This same feature will also indicate, by automatic alarms to the technical attendant, a failure of the transmitter or a false operation, should the transmitter radiate for any reason other than a signal from the remote control equipment.

The receiver is conventional in design: double-conversion superheterodyne with two grounded-grid radio-frequency stages. The electronic squelch of the receiver has been disabled and the normal noise voltages developed in the receiver are used to control a carrier-operated relay. The relay contacts are connected in such a manner that an idle receiver has a ground applied on the grid of the audio output stage. When a carrier is received and the receiver quiets, this ground is removed and transferred to a control circuit which indicates to the remote control equipment that a signal is being received. The recovered modulation of the incoming signal is then allowed to pass through the receiver and ultimately to the aviation service operator.

Vertically polarized omnidirectional gain antennas were used at both Chicago and Detroit. At the Detroit station, arrangements were provided to permit observation of the effect of small changes in the height and to determine the need for height diversity. This can also be seen from Fig. 3.

The transmitters used at both stations were phase-modulated, having a nominal power output of 15 watts with very good frequency stability. The use of cavity filters in a diplexing arrangement enables the operation of the transmitter and receiver simultaneously from a common antenna.

Control Equipment

In planning for this new service it was decided that the system arrangements should be the same, at least in the beginning, as the existing land mobile common-carrier services. This permits utilization of the Western Electric *G2* control terminal, shown in Fig. 4, which has proved very satisfactory as the intermediate connecting apparatus between the radio equipment and the "Aviation Service" operator, who supplies the final connection to the land telephone. The operator positions are shown on Fig. 5.

The control terminal does many things to simplify the use of radio circuits by the traffic operators, but its principal functions are to convert 4-wire to 2-wire operation, supply signaling tones for dialing the mobile station, and maintain a relatively constant audio volume to modulate the transmitter. These are discussed briefly as follows:

1. The standard land telephone is connected to the central office, and ultimately to any other telephone in the nation-wide network by means of a single pair of wires

Vol.
Pt. 1
1958

Fig. 6. Control unit and noise-canceling handset

over which the user both talks and listens. Contrasted with this, the radio circuit has separate talking and listening equipments which break the communication path into two one-way circuits, called 4-wire operation. In the control terminal, the talking and listening paths are bridged to the 2-wire line by a resistance network which delivers the proper audio level from the receiver to the switchboard and also to the transmitting path for modulation of the base transmitter. By modulating the base transmitter with the received audio the station can function as a repeater and furnish mobile-to-mobile communication over the coverage area of the base station.

2. The signaling method adopted by the Bell System utilizes a 2-tone sequential system using the frequencies 600 and 1,500 cycles per second. The arrangement is such that the tones are sent alternately, each transition of tone resulting from a pulse of the operator's dialing equipment. Since the number of pulses corresponds to the value of the digit dialed, the number of tone transitions is equal to the dialed digit. The mobile selector will advance one step for each transition of tone. If the selector is set up properly, a signaling contact will close when the dialing is completed. Five-digit telephone numbers will be assigned, the sum of the digits being equal to 23, 24, 25, or 26, with the digit 1 not used, and zero equal to 10. The digit 1 is not assigned because it is automatically transmitted as a clearing signal to the mobile receivers to set all selectors to the start position at the beginning and end of the dialing period.

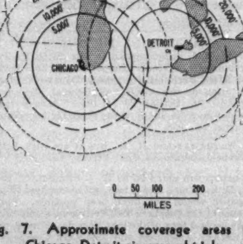

Fig. 7. Approximate coverage areas for Chicago–Detroit air–ground trials

3. Due to the nature of the telephone plant and telephone users, there is the additional problem of attempting to provide suitable modulation of the transmitter on every call from any telephone. The range of audio levels received at the aviation switchboard from land subscribers is expected to be from 0 volume units to −40 volume units, the distribution following a normal distribution curve. To compress this range of volumes to values which will allow good modulation on the great majority of transmissions, the terminal includes a self-adjusting variable-gain amplifier which will deliver zero ±4 volume units to the transmitting cable pair.

The electrical noise interference on board the *DC-3* was found to be inconsequential at these frequencies. The high ambient acoustic noise in the plane was largely overcome by the use of a noise-canceling microphone. The use of a conventional handset receiver as shown in Fig. 6 permitted satisfactory reception over the high airplane noise.

Results

A large volume of propagation data has been obtained by recording the field strength from the plane while in flight along various radials and at several different altitudes. Analysis of these data have not been completed at this time, but it appears with the powers and antennas used, that coverage is confined to regions lying well above the radio horizon which is the optical horizon modified by a factor of 4/3 to account for average refraction in the atmosphere. For example, with the 50 foot antenna at Detroit, the radio horizon to a plane at 10,000 feet is 150 miles. In actual practice the range obtained over relatively flat terrain was some 110 to 125 miles. Along a radial where the terrain fell off toward the lake in a manner to add to the effective height of the Detroit station, the range was some 25 miles greater. With the 535-foot base station antenna at Chicago ranges approaching the radio horizon were obtained. To a plane flying at 10,000 feet the radio horizon is approximately 175 miles. This is indicated on Fig. 7, which shows the approximate coverage areas of the Chicago and Detroit stations to aircraft at altitudes of 5,000, 10,000, and 20,000 feet.

Fig. 8. Location of antenna on DC-3 test aircraft

At the coverage limits the service was found to cut off in an abrupt manner. Particular attention was given to lobing effects caused by interaction of direct and ground reflected waves as has been so adequately described in the papers by Bureau of Standards personnel.[1] It appears that the lobing structure is less well defined than theoretical considerations would indicate, due presumably to the presence of multiple reflections from terrain irregularities. Lobes were found to be more numerous from the Chicago station using the 535-foot antenna as would be expected from theoretical considerations.

The antenna installation on the General Motors Corporation *DC-3* as shown in Fig. 8 resulted in a nonuniform pattern which means that the coverage range will depend somewhat on plane orientation.

When the plane flew through the region directly above the ground station, wide excursions of field strength were experienced but no "cone of silence" could be observed.

Problems

Development of an adequate nationwide air-ground service will require the solution of several outstanding problems. As has been touched on previously, allocation of a suitable band of frequencies is a prerequisite. An air-ground system using known techniques could be developed to operate in almost any band below 1,000 mc. However, use of frequencies between 100 and 500 mc would offer important advantages over higher frequencies such as earlier availability of equipment, lower cost, and better radio-propagation characteristics. It is estimated that a public radiotelephone service for aircraft will require 40-50 channels on a frequency-modulation basis to provide for the traffic which will develop in the next 8-10 years.

As was mentioned earlier, the present service is operating under a developmental grant from the FCC and, without further authorization from the Commission, service must end in September 1959. The existing trial has received the enthusiastic support of the entire aviation industry. An immediate need exists for the present service not only to be continued, but extended to cover the more important air lanes. The Bell System, therefore, on March 31, 1958, petitioned the FCC as a first step to extend the service to the east. The service would then cover cities originating one third of all commercial air travel in the United States and more than one fourth of all private flights. The addition of three stations near Pittsburgh, Pa., Washington, and New York, N. Y., should provide a coverage corridor 200 miles wide extending from 100 miles west of Chicago to the East Coast.

High-flying aircraft have a greater transmission range than do low-flying aircraft. For example, the range as limited by the radio horizon is less than 100 miles for a plane flying at 4,000 feet and may be in excess of 250 miles for a plane flying at 40,000 feet. It is evident that any system engineered to provide coverage for a particular altitude would result in the following:

1. Gaps in coverage between base stations for aircraft flying below this altitude.
2. Interference due to multiple reception of base station signals by aircraft flying above this altitude. The cochannel interference problem demonstrated by the tape recording can be considerably more severe unless careful attention is paid to this factor.

One problem which must be considered is that of maintaining a continuous conversation to an airplane flying between two base-station coverage areas. Liberal use of extensive telephone plant may be necessary to avoid the inconvenience of reestablishing the connection.

Radio Attenuation at 11 Kmc and Some Implications Affecting Relay System Engineering

S. D. HATHAWAY
NONMEMBER AIEE

H. W. EVANS
NONMEMBER AIEE

INCREASING use of the common-carrier microwave-frequency bands at 4 and 6 kmc (kilomegacycles) has directed attention to the next higher band at 11 kmc. All three bands are subject to atmospheric fading, but propagation at 11 kmc differs from that at the lower frequency bands chiefly in its vulnerability to rain. Knowledge of the statistics of the excess path loss caused by rain is a necessary prerequisite to 11-kmc system design, and therefore an experiment was undertaken to extend the modest body of available knowledge.

The effects of rain on microwave radio propagation have been calculated by Ryde and Ryde.[1,2] The radio energy is absorbed and scattered by the rain drops, and these effects become more pronounced at the higher microwave frequencies where the wave length and the raindrop diameter become more nearly comparable.

The excess attenuation caused by rainfall depends on the number of drops per unit volume in the radio path, the square of the drop diameter, and a complex factor representing the ratio of the total energy absorbed and scattered by a single drop to the energy in that area of the wavefront equal to the projected area of the drop.

Laws and Parsons[3] observed the distributions of drop sizes for various rates of fall on a horizontal surface, using the method of Bentley.[4] (The Bentley method involves exposing trays of sifted flour to the rainfall, baking the flour to solidify the pellets formed by impinging raindrops, and then sorting the pellets by size. The flour has been calibrated by generating drops of known size, so that drop size can be determined from the pellet size.) The higher the rainfall rate, the larger the drops, and also the greater the spread in size of drops. Ryde computes the number of drops per unit volume from the data of Laws and Parsons by applying the terminal velocity appropriate to the drop mass.

The excess path loss per mile according to Ryde for the three common-carrier frequency bands of 4, 6, and 11 kmc, is shown in Fig. 1 for various rates of rainfall. (It is interesting to note that from his computations Ryde concludes that the excess attenuation caused by hail is in the order of one-hundredth that caused by rain, that ice crystal clouds cause no sensible excess attenuation, and that snow produces very small attenuation, even at

The authors are indebted to K. J. Frolund, G. H. Swan, D. K. White, and others, without whose help this paper would not have been possible. The assistance of the Southern Bell Telephone Company and the central area of the long lines department of the American Telephone and Telegraph Company is deeply appreciated.

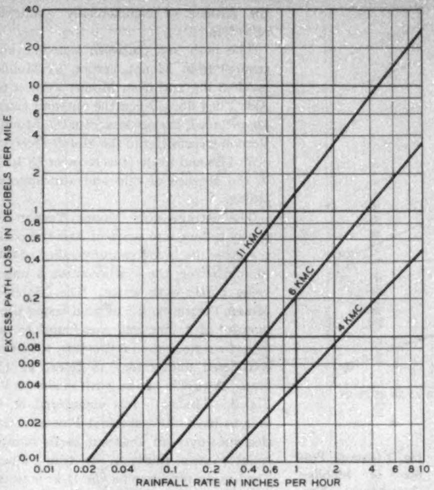

Fig. 1 (left). Rain attenuation versus rainfall rate (theoretical, after Ryde and Ryde)[1]

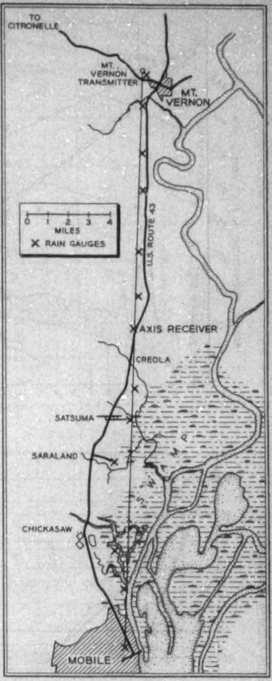

Fig. 2 (right). Map of Mobile–Axis–Mount Vernon radio path

the excessive rate of fall of 5 inches per hour.)

Many rainfall data are available for point locations, but very little is known about the relationship between the rate of fall at a single rain gaging point and the profile of rate of rainfall along a radio path. Furthermore, most rainfall data are in terms of fairly long discrete intervals, such as 30 minutes or one hour, and the relationship between hourly and instantaneous rates of fall is not perfectly known.

Bussey[5] has analyzed rainfall data for one year from the Muskingum River watershed in Ohio,[6] and finds that the annual distribution of 1-hour point rates is approximately the same as an annual distribution of instantaneous 50-kilometer path rates. He further suggests that 10-minute point data may apply to an 8-kilometer path, 30-minute data to a 25-kilometer path, etc.

It was the purpose of the experiment described here to seek confirmation of Ryde's relationship between excess path attenuation and instantaneous rate of rainfall, and to measure the profile of rate of rainfall along a radio path in hopes of finding correlation with rainfall measured at a single point. It was expected that this information would be useful in determining design parameters for 11-kmc radio-relay systems and for suggesting the conditions under which they be used.

The experiment consisted of operating a radio path of a length typical of short-haul radio-relay systems in a heavy-rain area for a year. Instrumentation included devices for measuring excess radio path loss, and rain gages along the path at intervals short enough to define the rainfall profile.

Radio Path

The requirements that determined the choice of the radio path were:

1. Heavy rainfall, both in rate and depth.
2. Length of about 25 miles, which is considered typical of possible 11-kmc application, with the possibility of a second receiver mid-way in the path so that some feel of interpolation versus length would result.
3. All-weather highway parallel to and very near the path, to permit access to rain gages.
4. Existing structures and buildings for antennas and radio equipment.
5. Preferably equipped with an operating 4-kmc radio-relay system, so that some comparison could be made between 4- and 11-kmc propagation.

Literally hundreds of possible paths were examined. The choice narrowed quickly to the Gulf Coast region because of the high incidence of heavy rainfall and the great total rainfall which is in the order of 60 inches per year. (Annual depths of about 150 inches occur in the north Pacific Coast rain forests, but surprisingly the rate of fall is quite low.) Finally a path was selected between Mobile and Mount Vernon, Ala., 27.7 miles long, approximately north and south, and parallel to a good highway, as shown in Fig. 2.

Arrangements were made to locate the transmitter at the Mount Vernon *TD-2* 4-kmc radio-relay station, and an 8- by 12-foot plane reflector, specially made to be flat to 1/16 inch, was mounted at the 300-foot level of the *TD-2* antenna tower. The reflector was illuminated by a 5-foot parabolic antenna on top of the transmitter equipment housing, using a buttonhook feed constructed of commercially available waveguide pieces. The gain of the antenna system at Mount Vernon was 44.2 db (decibels), 1.2 db greater than the gain of the parabolic antenna alone.

At Mobile, a similar antenna system for the receiver was placed on the *TD-2* tower atop the telephone building; but, because this tower was only 85 feet tall, a 6- by 8-foot plane reflector was used with the 5-foot parabolic antenna. The gain of the antenna system at Mobile was 42.8 db, 0.2 db less than that of the parabolic

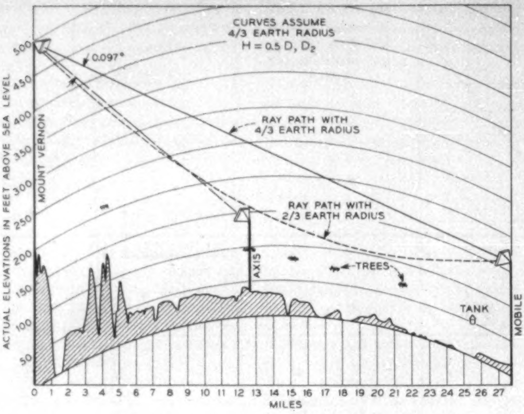

Fig. 3 (above). Profile of Mobile–Axis–Mount Vernon radio path

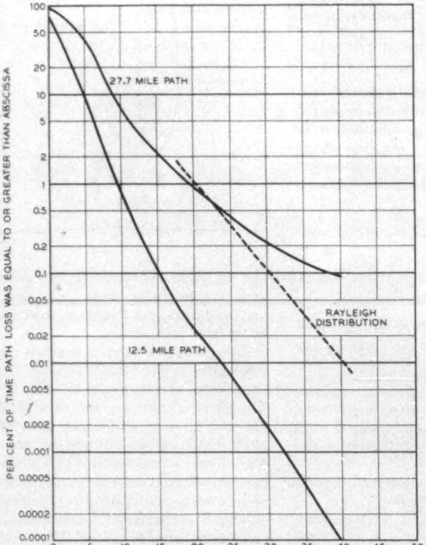

Fig. 4. Distribution of selective fading, March 1, 1956, through July 31, 1956

antenna alone because of the small spacing between the antenna and the reflector.

At a point 12.6 miles south of the transmitter at Mount Vernon, near Axis, Ala., a second receiving station was constructed. It used a 104-foot path-loss testing tower,[7] with a 3-foot parabolic antenna having a gain of 37.1 db mounted directly on the receiver front end, which could be run up and down the tower on a carriage. The tower was located directly in the path from Mount Vernon to Mobile.

The antenna sizes were chosen to produce roughly equal received signal levels at Mobile and Axis, and to produce as large a received signal as was consistent with physical stability of the towers and the flatness of commercially available reflectors.

The path loss (between isotropic antennas) from Mount Vernon to Mobile is 146.3 db, and from Mount Vernon to Axis 139.4 db. When the antenna gains are included, the net loss from the Mount Vernon transmitter to the Mobile receiver is 59.4 db and to the Axis receiver 58.1 db in the absence of rain and atmospheric fading.

The terrain near Mount Vernon is gently rolling, and south of Axis the path traverses the broad swampy valley of the Mobile River, the southernmost 3 miles being partly over water. The Mobile–Mount Vernon path had been tested previously[8] at 4 kmc and was found to be free of strong ground reflections, so it was considered unnecessary to retest at 11 kmc. A profile of the path is shown in Fig. 3. The path was engineered at 4 kmc to have one third first Fresnel zone clearance over an apparent earth radius equal to two thirds of its true value. The passive reflectors for the 11-kmc tests had to be mounted below the existing *TD-2* system antennas for physical reasons. The effect of lower antenna heights was to reduce the path clearance by 15 feet relative to the 4-kmc path. The limiting point in the path occurred 18 miles from the Mount Vernon end and with 60-foot trees the clearance was 36 feet when the effective earth radius was two thirds of its true value. At 11 kmc this was approximately 0.7 first Fresnel zone, which is considered adequate even for this area. The shorter path, Axis–Mount Vernon, had clearance in the order of four Fresnel zones, which was far more than sufficient.

Results

FADING

Fig. 4 shows the signal level distribution of both paths due to multipath fading for a 4-month period, omitting the effects of rain. The long path distribution exceeds Rayleigh for fades greater than 20 db. This would seem to indicate a strong stable reflection condition due either to ground reflections or to layer stratifications in the atmosphere. Since no path loss tests were made at 11 kmc, ground reflections cannot be ruled out. However, the path for the most part traverses land covered with low vegetation and pine forests, usually thought to be nonreflective. The *TD-2* system suffered similar fading, and it had been established that at 4 kmc the path was essentially nonreflective. Unfortunately, only a slow-speed strip recorder was moni-

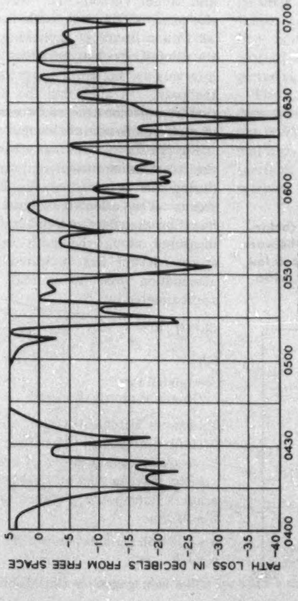

Fig. 5. Typical selective fading at 4 kmc

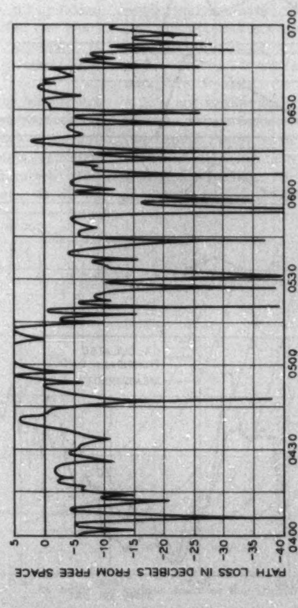

Fig. 6. Typical selective fading at 11 kmc

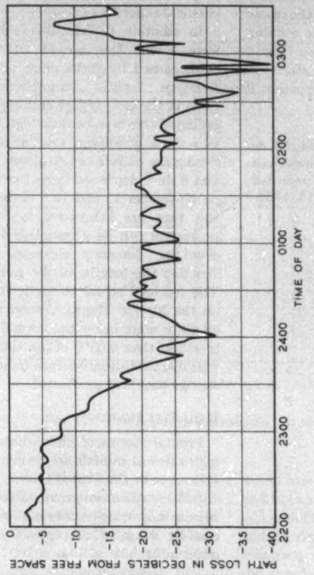

Fig. 7. Earth bulge fading at 4 kmc

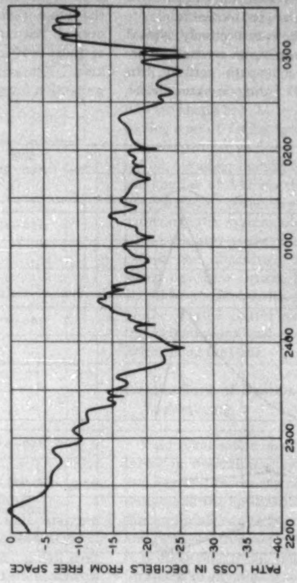

Fig. 8. Earth bulge fading at 11 kmc

toring the 4-kmc system and comparative distribution data are not available.

Figs. 5 and 6 show, respectively, typical 4-kmc and 11-kmc signal strengths during periods of multipath activity. In general, multipath fading on 4 kmc and 11 kmc began and ended at approximately the same time and followed the same over-all pattern. However, the number of fades was greater at 11 kmc than 4 kmc. The necessity of having diversity protection for such systems is apparent if they are to meet long-distance telephone circuit standards.

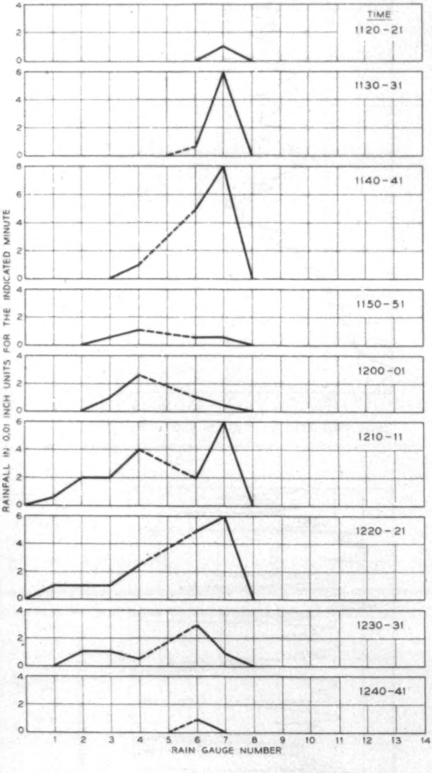

Fig. 9. Rainfall distribution over Axis–Mount Vernon path, March 15, 1956

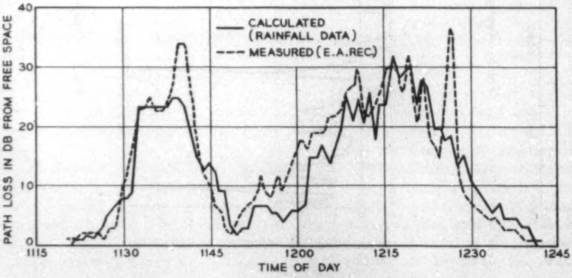

Fig. 10 (below). Correlation between rainfall and path loss, March 15, 1956

In addition to selective fading there were several long periods of depressed fields caused by earth bulge or obstructive-type fading. Atmospheric conditions in the Gulf region are favorable for fading of this type because high humidity and stable conditions exist at night and during the early morning hours. Figs. 7 and 8 show depressed fields that occurred on November 18 and 19. Since fades of this type are insensitive to frequency, protection can be accomplished only by providing adequate clearance and restricting the lengths of the radio paths. The received signal strength at 11 kmc on the Mobile–Mount Vernon path was 40 db or more below the normal received level less than 0.03% of the time for the year due to obstructive-type fading. The shorter path was unaffected.

RAIN ATTENUATION

Frontal storms of short duration and high rates of rainfall are common in the delta area of the United States. In general, these storms originate in the Gulf of Mexico and travel landward in a northeasterly direction. A typical storm arrived in Mobile on March 15, 1956, and passed diagonally across the radio test path between the small towns of Creola and Mount Vernon, Ala. Rain fell over this area of the test path from about 11:15 a.m. to 12:45 p.m. Fig. 9 shows the rainfall rate distribution at 10-minute intervals as the storm progressed across the path. In analyzing the data, such profiles were constructed for each minute of each significant rain event.

Fig. 10 shows the correlation between the measured and calculated signal levels during the progress of the March 15 storm. The calculated signal level is based on the effective 2-mile rainfall rate measured along the path during the storm. Ryde[2] has indicated that the attenuation due to rainfall can be approximated by

$$\text{db} = k\int_0^r R^{\alpha} dr$$

where

R = rainfall rate
r = length of propagation path

Professors Hitchfeld, Gunn, and East of McGill University, Montreal, Canada, have made computations of k and α for various wavelengths at 18 degrees centigrade. Extrapolation of their work yields for 11 kmc:

$k = 1.395$ db per mile per inch per hour
$\alpha = 1.3$

The rain gages on the Mobile–Mount

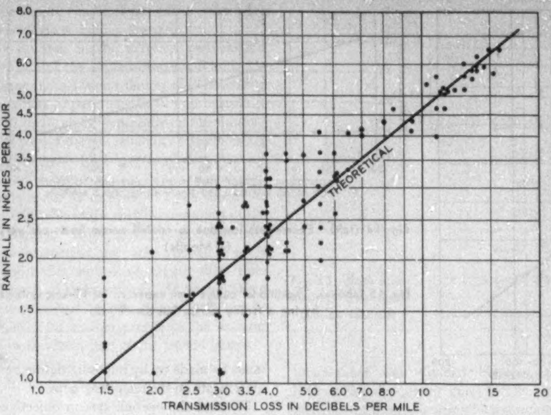

Fig. 11. Scatter plot of transmission loss versus rainfall rate

Vernon path were placed at approximately 2-mile intervals. The rainfall rate within one mile either side of a rain gage has been assumed uniform. Then, over any 2-mile path the attenuation due to rainfall is approximated by

$$\text{db} = 2kR^{\alpha}$$

The attenuation over the entire path is then the addition of the attenuations due to the 2-mile segments of the path:

$$\text{db} = 2k(R_1^{\alpha} + R_2^{\alpha} + \ldots + R_n^{\alpha})$$

The assumption of uniform rainfall within one mile either side of a rain gage is most surely inaccurate. However, it permits an approximate solution to the problem of attenuation due to rainfall that is not inconsistent with the measured values. Certainly a better correlation would have been obtained if the rain gages had been spaced closer together.

A number of rain events were analyzed and the data reduced to the equivalent 2-mile rate assuming uniform rainfall over the 2-mile spans. Fig. 11 is a scatter diagram showing transmission loss in decibels per mile due to precipitation versus precipitation in inches per hour. For comparison, Rydes' equation is plotted using the constant values suggested earlier.

The recording equipment at Mobile and Axis was arranged to record receiver input levels from 0 to 40 db below the normal input level [approximately −32 dbm (decibels referred to 1 milliwatt)]. The received signal strength was 40 db or more below the normal received level due to rainfall for 0.106% of the year on the Mobile–Mount Vernon path and 0.020% of the year on the Axis–Mount Vernon path. These figures indicate the expected order of outage time due to rainfall for single-hop 11-kmc radio systems having a 40-db fading margin and operating over similar paths in the Gulf Coast region. Fading margin is taken to mean the number of decibels the receiver input level might be reduced without the noise exceeding the system objective; outage time is defined as the time the noise does exceed the objective. Any predictions based on these figures for outage time would be pessimistic for most other areas of the United States since they reflect the attenuations due to severe rainfall found along the Gulf.

Implications of System Engineering

Rain attenuation is obviously a large factor in determining system reliability, and hence it reacts strongly on both the design and the application of the system. Since rainfall varies greatly in frequency and intensity from one region to another, it is important to be able to predict performance in any region so that the system as designed will have the widest possible application consistent with cost, and so that the applications engineer will know how to tailor those system parameters at his command to produce the degree of reliability desired.

It is not feasible for reasons of cost to measure rain attenuation in all parts of the United States, so it is necessary to use what rainfall data are available, and to couple the data, through what are thought to be reasonable assumptions, to

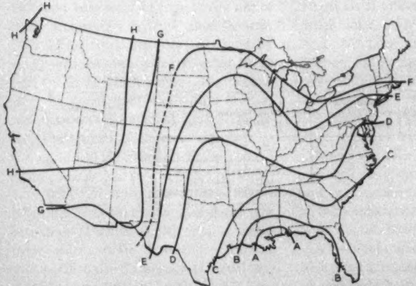

Fig. 12. Contours of constant path length for fixed outage time

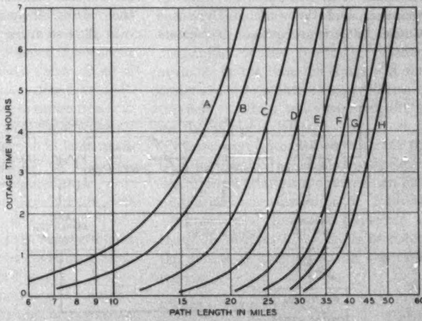

Fig. 13. Expected outage time in hours per year versus path length in miles for various areas of the United States

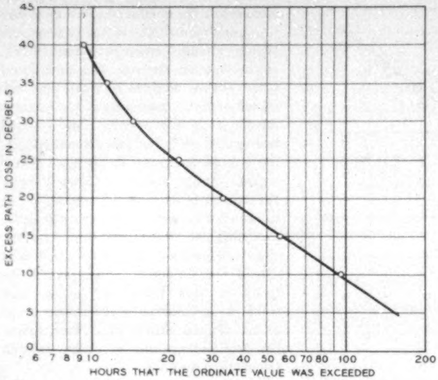

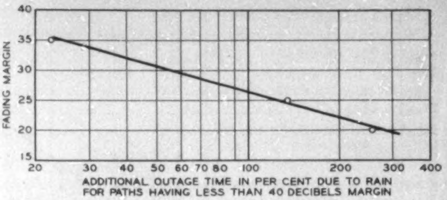

Fig. 14 (left). Excess path loss due to rainfall versus hours per year (at Mobile)

Fig. 15 (above). Additional outage time expected for 11-kmc systems having a fading margin less than 40 db

the relationships between rainfall and attenuation. The validity of the predictions rests clearly on the validity of the assumptions, and it is to be expected that further refinements in predicting rainfall outage will result from observing the performance of early 11-kmc systems.

As an approach to the problem of predicting outage time due to rainfall for all areas of the country, it has been assumed that the annual distribution of one-hour point rates is indicative of the annual distribution of instantaneous 30-mile path rates, along the lines suggested by Bussey.[5] This is equivalent to assuming a fixed storm pattern moving at 30 miles per hour in the direction of the path. Furthermore, it has been assumed that the frequency of occurrence of severe rainfall of the type measured in the Mobile area will be reduced in other parts of the country in proportion to the distribution of annual point rates of one inch or more per hour. Fig. 12, based on these assumptions and the work of Dych and Mattice,[9] illustrates contours of constant path lengths for fixed outage times for different areas of the United States. Fig. 13 shows the expected outage time due to rainfall for various path lengths in different rain areas of the United States. Curves *A* through *H* of Fig. 13 correspond to the general areas described by the contours on Fig. 12. The longer paths have been weighted somewhat to take account of less severe rainfall covering larger areas than storms typical of the Gulf region.

In engineering a complete 11-kmc radio-relay system, the rain outages of the individual hops must be added to obtain the performance for the system. Also, it is desirable to lay the system out in such a manner that the individual hops meet the same objective. From a practical standpoint this will not always be possible. Sometimes it is necessary to have one or more hops of a system electrically long; they will have insufficient fading margin and hence contribute more than their share of outage time. From the over-all system viewpoint this "excess" must be made up by imposing tighter requirements on the remaining hops.

To meet the over-all system objective it becomes necessary to know the contributions of the long hops, those having a fading margin less than 40 db. Fig. 14 shows excess path loss due to rain versus hours per year for the Mobile–Mount Vernon path. The shape of this curve is nearly identical with Bussey's curve on cumulative distribution for point rates at Washington, D. C. If the shape of this curve is assumed to be representative for other areas of the country, then the additional outage time for path lengths given by Fig. 13 can be estimated for hops having a fading margin less than 40 db. The data shown in Figure 14 have been rationalized and shown in Fig. 15 as an estimate of additional outage time.

Sometimes it is practical to shorten a proposed path to bring the fading margin up to 40 db. An approximation of the necessary reduction in path length can be made if uniform rainfall rate is assumed over the path. Under this condition Ryde shows the attenuation due to rainfall to be directly proportional to the path length. Thus the path length given

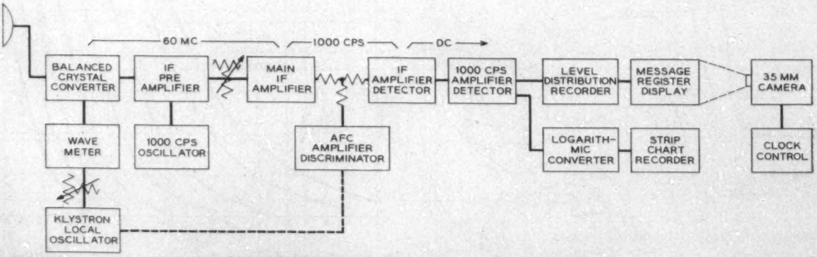

Fig. 16. Block schematic of radio receiver and recording equipment

in Fig. 13 can be shortened to correct for insufficient fading margin.

Rainfall in the extreme southeastern region of the United States will limit 11-kmc radio systems having a 40-db fading margin to path lengths of approximately 10 to 15 miles, depending on the number of hops if normal reliability objectives are to be met. Path lengths of 20 to 30 miles should be acceptable in the central area and path as long as 35 miles should be acceptable in the northwestern part of the country. However, in existing short-haul radio systems, the paths average 22 to 24 miles due to considerations other than those of propagation. It would then appear that 11-kmc systems will not be penalized unduly except in the extreme southeastern part of the United States.

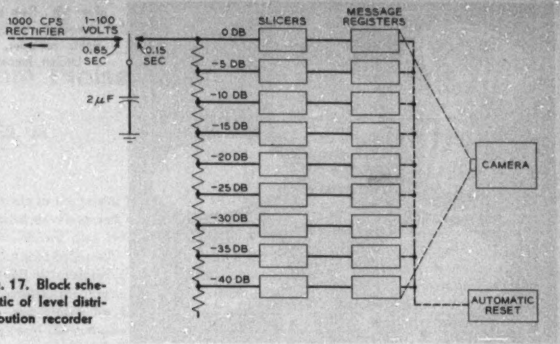

Fig. 17. Block schematic of level distribution recorder

Instrumentation

Transmitter

The transmitter employed a small commercially available klystron whose output was 0.5 watt. A variable probe was used to match the klystron to the waveguide to the antenna, and a 20-db directional coupler sampled the output so that frequency could be measured and the output power-monitored. The frequency stability was such that it was not necessary to use automatic frequency control. Since the a-c line was subject to frequent failure (a natural result of the thunderstorms whose rainfall provided the reason for the experiment), a strip-chart recorder with a mechanical clock drive was used to monitor the transmitter output.

Receiver

The receiver was adapted from equipment designed to record path loss at 4 kmc, which was in turn adapted from equipment designed to measure path reflections.[8] It is shown in block schematic in Fig. 16. (An extensive path-loss measuring program was carried out in 1947–1950 at 4 kmc prior to commercial use of those frequencies by the Bell System. This 4-kmc equipment was designed by H. C. Franke, and was converted to 11 kmc by S. D. Hathaway.) The normal received signal level was −32.2 dbm at Mobile and −31.1 dbm at Axis. The receiver was arranged to record signals from 0 db to −40 db relative to the normal signal.

A balanced converter supplied by a local klystron oscillator modulated the incoming 11.4-kmc signal to a 60-megacycle intermediate frequency. In the preamplifier the 60-megacycle signal was amplitude-modulated with 1,000 cps (cycles per second). The output of the preamplifier was divided between an intermediate-frequency amplifier feeding a frequency discriminator which provided automatic frequency control to the local klystron oscillator, and an amplitude detector where a 1,000-cps signal reasonably proportional to the microwave input signal over a 50-db range was recovered. The 1,000-cps signal was amplified and rectified at a level suitable to operate the display equipment.

Display Equipment

Two types of display equipment were used:

1. A level distribution recorder with a range of 40 db, which operated message registers which were photographed automatically on 35-millimeter film every 0.1 hour.
2. A strip-chart recorder with a logarithmic converter to produce a scale linear in decibels over a 50-db range.

Level Distribution Recorder

The electronic level distribution recorder to be described was developed in 1946 to replace a relay device that had been used for many years to study distributions of talker volume and telephone circuit noise. This circuit was conceived by L. Y. Lacy and developed by C.R. Eckberg for mobile use in connection with investigations of very-high-frequency transmission to vehicles, and later modified by H. C. Franke for use in microwave propagation measurements.

A series of nine d-c slicer circuits, each arranged to operate at an input of one volt, was connected to a voltage divider at 5-db intervals, thus covering a range of 40 db, as shown in Fig. 17.

A 2-microfarad capacitor was connected by a relay actuated by a sychronous timer to a cathode follower output of the 1,000-cps rectifier for 0.85 second. Then for 0.15 second the capacitor was connected to the voltage divider slicer circuit. The slicer circuits were arranged to drive message registers (counters) with the polarity such that if the slicer threshold was exceeded, the message register would not count; if the slicer threshold was not exceeded, the message register counted. Thus an input of 100 volts (normal signal) caused no counts. An input of 0.9 volt (41 db fade) caused all message registers to count. (Other level distribution recorders have been built with cross-gating between the slicers so that only the message register corresponding to the level just exceeded will operate. This type yields a histogram data presentation, whereas radio fading data are usually presented as a cumulative distribution.)

Standard 14-type telephone message registers were used, and a neon tube was connected across each message register for easy observation of individual counts. Some message register units were arranged with an automatic reset mechanism that reduced all message register readings to zero hourly. This simplified reducing the data since smaller numbers had to be dealt with, but the delicate mechanism of the resettable registers available at the time the equipment was designed led to maintenance problems in the field, so these units were rebuilt to use the simpler registers.

Means were provided to calibrate the level distribution recorder in a preliminary way from an accurate d-c source, but final calibration was always made from an accurate signal generator connected to the radio receiver input, so as to reduce the effects of nonlinearity in the radio receiver.

Camera Equipment

Pictures of the message register were taken every 0.1 hour by a 35-millimeter

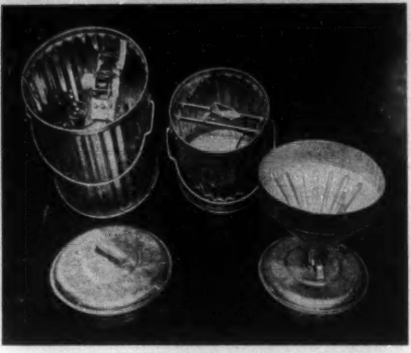

Fig. 18. Rain gage assembly, left to right: recorder, tilt bucket, funnel

camera adapted from a movie camera, under the control of a 24-hour electric clock which was included in the message register panel so that the time of each picture was recorded. Auxiliary message registers recorded the total number of measurements and the date, the latter register being actuated by the 24-hour clock. The message register units and cameras were enclosed in a trunk to reduce spurious illumination. A projection film reader was used to transfer the data to a data book for analysis.

LOGARITHMIC CONVERTER

The logarithmic converter accepted a d-c input voltage in the range −0.3 to −100 volts (as developed by the 1,000-cps detector) and changed it to a direct current proportional to the logarithm of the input voltage, with a range of 0–1 milliampere for the operation of a strip-chart recorder.

The d-c input voltage was chopped at a 60-cps rate and applied to a differentiating circuit followed by a d-c slicer circuit. The time that the differentiated wave exceeded the threshold of the slicer was proportional to the logarithm of the input voltage, so that the output of the slicer was a 60-cps wave with pulse-length modulation proportional to the input voltage in decibels. This output was filtered and applied to a strip-chart recorder to provide a linear 0–50-db recording. (It was found that imperfect filtering was desirable, in that a small amount of the 60-cps component improved the response of the strip-chart recorder to small changes in input.)

This display was limited by the slow response of the strip-chart recorder, whose time constant was about 0.5 second, so that the strip charts were used chiefly for monitoring and quick scanning of data.

RAIN GAGES

Automatic recording tilt-bucket rain gages, designed by L. E. Hunt, were placed approximately every 2 miles along the radio path, as shown in Fig. 2. The exact locations were determined by considerations of accessibility, since many of the roads across the radio path were little more than swamp traces. Also, an effort was made to minimize the effect of nearby objects such as trees and buildings.

The rain gage mechanisms, shown in Fig. 18, were proportioned so that the bucket tilted after each 0.01 inch of rain fell. A magnet attached to the tilt bucket closed the contacts of a glass-sealed switch during the instant of tilting. (Earlier models used open contacts which worked well in the laboratory but proved unsatisfactory under field conditions.)

RAIN GAGE RECORDERS

Because of the sparse wire facilities along the path, it was impossible to bring each rain gage circuit to a central recorder so individual strip-chart recorders were used at each rain gage. These used teletypewriter tape driven by a clock at the speed of 0.1 inch per minute (a little over 11 feet per day). Before this method was decided upon, the usual troubles of changes of paper dimensions caused much experimentation with chart drive; pins in the drive drums were superseded by a neoprene-band friction drive. Also, several types of clocks were tried: automobile electric clocks, precision automobile electric clocks, large spring-wound clocks, and finally governor-controlled d-c motors. None yielded the precision of timing desired, so that it was necessary to interpolate to avoid errors in correlating the individual rain gage records for particular rain events. (The improvements in the recorders were made by K. J. Frolund.) The strip-chart recorders also incorporated a stylus driven by an electromagnet that punched a tiny hole in the tape each time the rain gage bucket tilted. Thus, at the cloudburst rate of fall of 8 inches per hour, the punch marks were just over 0.01 inch apart, so that careful examination under a strong glass was required.

Performance of Class B Audio Amplifiers with Random Noise Signals

THERON USHER, JR.
ASSOCIATE MEMBER AIEE

DURING the past 3 years new problems in audio amplifier design have arisen as a result of using low-distortion high-power audio amplifiers for driving electrodynamic vibration exciters.[1] Modern vibration testing procedures require that random noise forces be used to excite the test specimens. This requirement has arisen from efforts to reproduce the actual environments occurring in airborne guided missiles.[2,3]

In order to obtain random vibratory forces from the vibration exciter, the currents and voltages produced by the power amplifier must also be random. Previous analyses of power amplifier performance have dealt only with the use of sinusoidal signals.[4,5] Due to the fundamental differences between random signals and sinusoidal signals,[6] the necessity for analyzing the performance of audio amplifiers for noise excitation becomes evident.

In particular, this paper considers the operation of the power stage of an audio amplifier which is excited by a band-limited random voltage. The power stage is assumed to contain triodes in class *B* push-pull operation. For simplicity of the driver circuit, the operation of the power stage is limited to the negative grid region. The power stage of the amplifier is coupled to the vibration exciter by means of a high-quality audio output transformer. For the purpose of keeping the results as general as possible, the vibration exciter is treated as a load with a complex impedance, the magnitude and angle of which vary widely over the frequency band of the noise signal.

The operational limitations of the amplifier power stage are discussed in the following sections, and are related mathematically to the noise voltages and currents in the power stage. The mathematical development draws heavily from noise theory and probability theory as introduced by Rice.[6] Finally, a graphical method is developed for selecting the output transformer turns ratio that provides the best match for the amplifier power stage and the complex impedance load.

Circuit Diagram and Nomenclature

Fig. 1 shows the circuit diagram for the power stage of the audio amplifier. Each triode is assumed to be biased to plate current cutoff, and restricted in operation to the negative grid region.

The various currents and voltages are defined in the following. In general, a lower-case symbol for voltage or current indicates an instantaneous value or a function of time. A bar above a time-varying quantity indicates the average or mean value of the quantity.

i_1 = plate current of upper triode, amperes (amp)
i_2 = plate current of lower triode, amp
v_{p1} = plate voltage of upper triode, volts
v_{p2} = plate voltage of lower triode, volts
v_1 = voltage across upper half of transformer primary, volts
v_2 = voltage across lower half of transformer primary, volts
i_b = plate supply current, amp
E_{bb} = plate supply voltage, volts
E'_{bb} = apparent plate supply voltage, volts
v = voltage across load impedance, volts
i = load current, amp
$Z(f)$ = complex load impedance $= R(f) + jX(f)$, ohms
N = transformer turns ratio, half primary to secondary
N_O = optimum transformer turns ratio
W_p = average plate power dissipation for both triodes, watts
σ_e = rms value of noise voltage at load, volts
σ_i = rms value of noise current at load, amp
R_p = plate resistance of power triode for zero grid bias, ohms
R_n = equivalent noise resistance of load, ohms
Z_n = equivalent noise impedance of load, ohms
$V(f)$ = spectral density of noise voltage at load, volts^2/cps (per cycles per second)
$I(f)$ = spectral density of noise current at load, amp^2/cps
$W(f)$ = spectral density for actual noise power at load, watt/cps
k = nondimensional level factor for spectra
$V'(f)$ = portion of $V(f)$ containing frequency variation, volts^2/cps
$I'(f)$ = portion of $I(f)$ containing frequency variation, amp^2/cps
P_c = probability of clipping or positive grid operation in power stage
K_1 = nondimensional parameter
K_2 = nondimensional parameter
y = nondimensional parameter

Limitations on Amplifier Operation

Two basic limitations on the operation of the power stage of the amplifier should be considered. First, the average plate dissipation of each power triode must not exceed the manufacturer's rating. The noise currents and noise voltages in the power stage may be assumed to be very nearly gaussian, and a mathematical expression for the plate dissipation can be derived.

The second limitation, that of negative grid operation, has previously been mentioned. This limitation will now be discussed in some detail. It is assumed that the signal voltages in previous stages of the audio amplifier are ideal, or have gaussian probability density functions, and that negligible clipping occurs in these stages. However, if the signal voltage has a large enough amplitude at the input to the power stage, either grid may draw current and cause excessive grid clipping in the power stage. Theoretically some clipping of the noise voltage and current always occurs if the input is perfectly gaussian, no matter how small the signal level, but clipping rapidly becomes insignificant as signal amplitude is reduced.

It can be seen that the objectives of high output and low distortion are not mutually compatible. A compromise between the two objectives may be achieved by having a specification that limits the clipping to a practical, but small, amount. The most convenient way to state this specification is to limit the probability of clipping, or of attempted positive grid operation, to a small value.

The probability approach to the problem of evaluating the amount of clipping

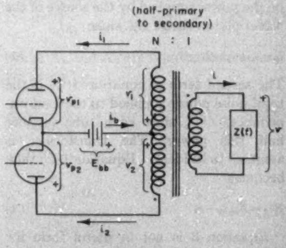

Fig. 1. Circuit diagram for the amplifier power stage

Paper 58-1237, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted June 4, 1958; made available for printing August 26, 1958.

THERON USHER, JR., is with Yale University, New Haven, Conn.

The work described in this paper and in the thesis listed as reference 1 is an outgrowth of development work for high-power audio amplifiers done by The MB Manufacturing Company, New Haven, Conn. The author wishes to thank them for making publication of this paper possible.

is advantageous because of the complexity of the problem. Due to the random nature of the signal, and the variation of load impedance with frequency, the path of operation for voltage and current on the plate characteristics of the power stage is nonrepetitive. This consideration alone suggests probability theory as the only reasonable approach for providing an analytical solution to the problem.

In the following sections the two limitations for amplifier operation are analyzed mathematically. From the previous arguments, it can be seen that the power stage is operating in an optimum fashion when the conditions of rated average plate dissipation and rated probability of clipping occur together. A graphical method for determining the optimum transformer turns ratio, N_O, for the foregoing condition is also described.

Average Plate Power Dissipation

The average plate power dissipation of an electron tube has been shown by many electronics texts[7] to be the average of the product of the plate voltage as a function of time and the plate current as a function of time. Thus the average plate dissipation for both tubes in Fig. 1 is

$$W_p = \overline{v_{p1}i_1} + \overline{v_{p2}i_2} \tag{1A}$$

By symmetry,

$$\overline{v_{p1}i_1} = \overline{v_{p2}i_2}$$

and

$$W_p = \overline{2v_{p1}i_1} \tag{1B}$$

By reference to Fig. 1, and basic theorems of probability theory concerning mean or average values,[8] the following simplifications of equation 1(B) may be accomplished.

$$W_p = 2\overline{(E_{bb}-v_1)i_1} = 2E_{bb}\bar{i}_1 - 2\overline{v_1 i_1} \tag{1C}$$

The first term of equation 1(C) is seen to be the power supplied by the source of the direct plate voltage E_{bb}, since

$$\bar{i}_b = \bar{i}_1 + \bar{i}_2 = 2\bar{i}_1 \tag{2}$$

The second term of equation 1(C) is the total noise power supplied to the load impedance, $Z(f)$, since each tube supplies half this power. The transformer is assumed to be ideal. Equation 1(C) then becomes

$$W_p = E_{bb}\bar{i}_b - \overline{vi} \tag{3}$$

Equation 3 is not in useful form for computational purposes. To obtain a useful form, the terms i_b and $\overline{vi}$ must be evaluated. The plate supply current can be expressed as a function of the load current:

$$i_b = \frac{1}{N}|i| \tag{4}$$

If the load current, i, is gaussian, or very nearly gaussian, the average plate supply current is defined by equation 5(A)

$$\bar{i}_b = \int_{-\infty}^{\infty} \frac{1}{N}|i| \frac{1}{\sqrt{2\pi}\sigma_l} \exp\left[-\frac{i^2}{2\sigma_l^2}\right] di \tag{5A}$$

The integral in equation 5(A) has been evaluated,[8] and the average plate supply current is

$$\bar{i}_b = \sqrt{\frac{2}{\pi}}\frac{\sigma_l}{N} \tag{5B}$$

The rms load current σ_l is defined by the integral in equation 6, where $I(f)$ is the spectral density of the load current.

$$\sigma_l = \left[\int_0^\infty I(f)df\right]^{1/2} \tag{6}$$

Since $\bar{i}_b$ has been evaluated in terms of σ_l, it would be convenient to evaluate $\overline{vi}$ in terms of σ_l also. The physical significance of $\overline{vi}$ is that it is the average noise power supplied to the load. Mathematically, $\overline{vi}$ is a second moment of the joint probability density function for v and i. However, the evaluation of $\overline{vi}$ will make use of its physical significance.

The load impedance, $Z(f)$, can be resolved into its resistive and reactive components, both of which may be functions of frequency:

$$Z(f) = R(f) + jX(f) \tag{7}$$

The power dissipated per cps is then given by equation 8

$$W(f) = I(f)R(f) \tag{8}$$

The total noise power delivered to the load is the integral of equation 8 over the entire frequency band.

$$\overline{vi} = \int_0^\infty W(f)df = \int_0^\infty I(f)R(f)df \tag{9}$$

The computation in equation 9 can be simplified somewhat by recognizing the fact that the basic behavior of $I(f)$ as a function of frequency is usually specified by the requirements of a particular problem. It is desirable, however, to have the level of $I(f)$ as high as possible, under the operational limitations previously mentioned. Thus $I(f)$ can be split into a portion $I'(f)$, which describes the shape of the current spectrum as a function of frequency, and a factor k, which describes the level.

$$I(f) = kI'(f) \tag{10}$$

With this consideration in mind, it is possible to define an "equivalent noise resistance," R_n.

$$R_n = \frac{\overline{vi}}{\sigma_l^2} = \frac{\int_0^\infty I(f)R(f)df}{\int_0^\infty I(f)df} = \frac{\int_0^\infty I'(f)R(f)df}{\int_0^\infty I'(f)df} \tag{11}$$

It is easily seen from equation 11 that R_n is not dependent upon the absolute level of the current spectral density, and may be evaluated if the shape of the current spectral density is specified and the load impedance characteristics are known. In other words, R_n is not a function of σ_l.

Equation 3 is converted to a useful form by substituting the results found in equations 5(B) and 11.

$$W_p = \sqrt{\frac{2}{\pi}}\frac{E_{bb}}{N}\sigma_l - R_n\sigma_l^2 \tag{12}$$

Equation 12 is expressed in terms of quantities that can be easily computed or measured. For rated plate dissipation conditions, $W_p = W_{pr}$, and equation 12 may be rearranged to yield N in terms of σ_l.

$$N = \frac{\sqrt{\frac{2}{\pi}}E_{bb}\sigma_l}{W_{pr} + R_n\sigma_l^2} \tag{13}$$

Equation 13 will be used in a later section for describing the method of obtaining the optimum value for the turns ratio N_o.

Probability of Clipping

In order to evaluate the probability of clipping, it is necessary to define the var-

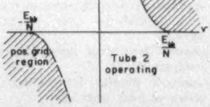

Fig. 2. Push-pull characteristics referred to secondary of output transformer

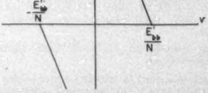

Fig. 3. Approximate zero grid voltage characteristics

ious regions of operation for the push-pull power stage. For analytical purposes, it is convenient to refer the push-pull characteristics to the load side of the output transformer, as shown in Fig. 2. The top half of the current-voltage plane corresponds to the condition when tube T_1 in Fig. 1 is operating and T_2 is cut off. The bottom half of the current-voltage plane corresponds to the opposite operating condition. The zero grid voltage curves in Fig. 2 are shown as dashed lines and the positive grid regions are shaded. The probability of clipping is evaluated by assuming ideal or gaussian probability density functions for load current and load voltage, and then computing the probability of finding both ideal variables jointly in the positive grid regions of Fig. 2.

Since v and i are related or nonindependent random variables, their ideal amplitude behavior is specified by the two-dimensional probability density function in equation 14.[8]

$$p(v,i)=\frac{1}{2\pi\sqrt{\sigma_e^2\sigma_i^2-\overline{vi}^2}}\times \exp\left[-\frac{\sigma_i^2v^2+\sigma_e^2i^2-2\overline{vi}\,vi}{2(\sigma_e^2\sigma_i^2-\overline{vi}^2)}\right] \quad (14)$$

It will be noted that the joint gaussian density function for v and i is completely described by the second moments of these variables, σ_e^2, σ_i^2, and $\overline{vi}$. The probability of finding both variables in the shaded areas of Fig. 2 is the double integral of the density function over these areas, as noted in equation 15.

$$P_c=\iint_{\substack{\text{shaded}\\ \text{areas}}} p(v,i)\,dv\,di \quad (15)$$

Due to the symmetrical nature of the problem, the integral in equation 15 can be simplified by integrating over the upper shaded area in Fig. 2, and doubling the results.

$$P_c=2\iint_{\substack{\text{upper}\\ \text{shaded}\\ \text{area}}} p(v,i)\,dv\,di \quad (15A)$$

The analytical problem is simplified greatly by approximating the zero-grid voltage curves in Fig. 2 by straight lines as shown in Fig. 3. The equation for the straight line in the upper half of the v-i plane is

$$v=\frac{E'_{bb}}{N}-\frac{R_p}{N^2}\,i \quad (16)$$

The voltage E'_{bb} is the "apparent plate supply voltage," and R_p is the plate resistance of the triodes. The straight-line approximation is very good except at low values of current. With equation 16, the limits of the double integral in equation 15(A) can be specified in a simple fashion. The differential segment of area in Fig. 3 further explains the specification of the limits. The result of combining equations 11, 14, and 15(A) is

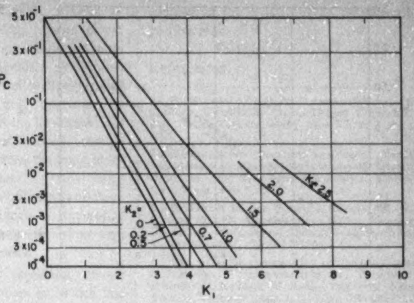

Fig. 4. Probability of clipping, P_c, versus K_1 for various values of K_2

$$P_c=2\int_0^\infty di\times \int_{\frac{E'_{bb}}{N}-\frac{R_p}{N^2}i}^{\infty}\frac{dv}{2\pi\sqrt{\sigma_e^2\sigma_i^2-R_n^2\sigma_i^4}}\times \exp\left[-\frac{\sigma_i^2v^2+\sigma_e^2i^2-2R_n\sigma_i^2vi}{2(\sigma_e^2\sigma_i^2-R_n^2\sigma_i^4)}\right] \quad (17)$$

The integrand in equation 17 is simplified by considering the definition for σ_e^2:

$$\sigma_e^2=\int_0^\infty V(f)df=\int_0^\infty I(f)|Z(f)|^2df \quad (18)$$

Next, the following definition for the "equivalent noise impedance" of the load is given:

$$Z_n=\frac{\sigma_e}{\sigma_i}=\left[\frac{\int_0^\infty V(f)df}{\int_0^\infty I(f)df}\right]^{1/2} =\left[\frac{\int_0^\infty kI'(f)|Z(f)|^2df}{\int_0^\infty kI'(f)df}\right]^{1/2} \quad (19)$$

It can be seen from equation 19 that Z_n is not dependent upon the magnitude of σ_e and σ_i, but is a constant, and may be calculated if $I'(f)$ and $Z(f)$ are known. With the result of equation 19, equation 17 becomes

$$P_c=2\int_0^\infty di\times \int_{\frac{E'_{bb}}{N}-\frac{R_p}{N^2}i}^{\infty}\frac{dv}{2\pi\sigma_i^2\sqrt{Z_n^2-R_n^2}}\times \exp\left[-\frac{v^2+Z_n^2i^2-2R_nvi}{2\sigma_i^2(Z_n^2-R_n^2)}\right] \quad (17A)$$

The integration process in equation 17(A) is further simplified by separating terms in the exponential and completing the square:

$$P_c=\frac{2}{2\pi\sigma_i^2\sqrt{Z_n^2-R_n^2}}\times \int_0^\infty \exp\left[-\frac{Z_n^2i^2-R_n^2i^2}{2\sigma_i^2(Z_n^2-R_n^2)}\right]di\times \int_{\frac{E'_{bb}}{N^2}-\frac{R_p}{N^2}i}^{\infty}\exp\left[-\frac{v^2-2R_nvi+R_n^2i^2}{2\sigma_i^2(Z_n^2-R_n^2)}\right]dv$$

$$=\frac{2}{2\pi\sigma_i^2\sqrt{Z_n^2-R_n^2}}\times \int_0^\infty \exp\left[-\frac{i^2}{2\sigma_i^2}\right]di\times \int_{\frac{E'_{bb}}{N}-\frac{R_p}{N^2}i}^{\infty}\exp\left[-\frac{(v-R_ni)^2}{2\sigma_i^2(Z_n^2-R_n^2)}\right]dv \quad (20)$$

Let

$$x=\frac{v-R_ni}{\sigma_i\sqrt{Z_n^2-R_n^2}}$$

and

$$y=\frac{i}{\sigma_i} \quad (21)$$

Then equation 20 becomes

$$P_c=2\int_0^\infty \frac{1}{\sqrt{2\pi}}\exp\left[-\frac{y^2}{2}\right]dy\times \int_{K_1-K_2y}^\infty \frac{1}{\sqrt{2\pi}}\exp\left[-\frac{x^2}{2}\right]dx \quad (22)$$

where K_1 and K_2 are nondimensional and are given by

$$K_1=\frac{E'_{bb}}{N\sigma_i\sqrt{Z_n^2-R_n^2}} \quad (23A)$$

and

$$K_2=\frac{\frac{R_p}{N^2}+R_n}{\sqrt{Z_n^2-R_n^2}} \quad (23B)$$

Related forms of the integral over x in equation 22 are tabulated,[9] but the defini-

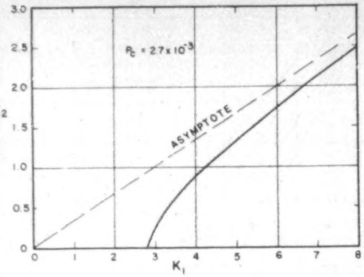

Fig. 5 (left). K_2 versus K_1 for constant P_c

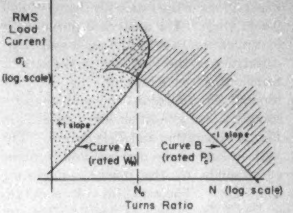

Fig. 6 (right). Graphical determination of optimum performance

tion for the normal probability distribution function will be used in equation 24(A).

$$F(\alpha)=\int_{-\infty}^{\alpha}\frac{1}{\sqrt{2\pi}}\exp\left[-\frac{x^2}{2}\right]dx \qquad (24A)$$

and

$$F(\alpha)=1-F(-\alpha) \qquad (24B)$$

In terms of the function $F(\alpha)$, which can easily be determined from tabulated integrals, the probability of clipping in equation 22 becomes

$$P_c(K_1,K_2)=2\int_0^{\infty}\frac{1}{\sqrt{2\pi}}\times \left\{\exp\left[-\frac{y^2}{2}\right]\right\}\{F[K_2y-K]_1\}dy \qquad (23)$$

It can be seen from equation 23 that P_c is a function of the nondimensional variables K_1 and K_2 only.

The integral in equation 23 has defied analytical evaluation for general values of K_1 and K_2, but has been evaluated numerically for several values of K_1 and K_2. The results are shown in Fig. 4, which shows P_c as a function of K_1, for various constant values of K_2. Two special cases of the integral in equation 23 have been evaluated. For $K_2=0$,

$$P_c(K_1,0)=F(-K_1) \qquad (24)$$

Also, when $Z_n\rightarrow R_n$ for a purely resistive load,

$K_1,\ K_2\rightarrow\infty$

but

$$\frac{K_1}{K_2}=\frac{E'_{bb}}{N\sigma_l\left(\frac{R_p}{N^2}+R_n\right)} \qquad (25)$$

and

$$\lim_{\substack{K_1\rightarrow\infty\\K_2\rightarrow\infty}} P_c(K_1,K_2)=2\left[1-F\left(\frac{K_1}{K_2}\right)\right]$$

$$=2F\left(-\frac{K_1}{K_2}\right) \qquad (26)$$

It has been mentioned that the probability of clipping must be limited to a small value in order that distortion be reasonably small. A typical value for P_c is 2.7×10^{-3}. This corresponds to the probability of a single gaussian random variable assuming a value greater than three times the rms value. The parameter K_2 is plotted as a function of K_1 for this typical value of P_c in Fig. 5. Equations 23(A) and 23(B) will be used with Fig. 5 in the next section to describe the graphical method for determining the optimum turns ratio, N_O.

Graphical Determination of Optimum Operating Conditions

As indicated previously, the power stage operates in an optimum fashion when the conditions of rated plate dissipation and of rated probability of clipping are satisfied simultaneously. The parameter used in the previous analysis which is indicative of the amplifier output is the rms load current, σ_l. When the amplifier is operating in optimum fashion, σ_l will have its largest possible value. The problem yet remains to determine the values of the amplifier parameters (E_{bb}; E'_{bb}; R_p; N) which will yield the maximum possible value of σ_l with regard to the specified amplifier limitations and the given load impedance.

Actually, a slightly more restricted aspect of this general problem will be considered. It will be assumed that the plate supply voltage and vacuum tube type have already been selected. This fixes the value of E_{bb}, E'_{bb}, W_{pr}, and R_p. The problem then becomes one of selecting the value of the transformer turns ratio that yields maximum output or maximum rms load current. Due to the complicated equations which describe the plate dissipation limitation and the signal clipping limitation, the solution can best be done graphically.

From equation 13, a graph of σ_l as a function of N may be constructed if E_{bb}, W_{pr}, and R_n are known. The shape of the typical curve resulting from the solution of equation 13 is shown on logarithmic co-ordinates in Fig. 6 and is labelled A. Points in the dotted area in Fig. 6 yield values for plate dissipation which are greater than the rated value. The shape of curve A can be deduced from equation 13.

At low values of σ_l, the $R_n\sigma_l^2$ term in equation 13 is negligible and N varies directly with σ_l. Thus the slope of curve A at low values of σ_l is very nearly unity. As σ_l increases, the slope increases and N reaches a maximum value. The region of negative slope for the rated plate dissipation curve is rarely of interest.

The next part of the graphical procedure involves finding and plotting the values of σ_l and N which satisfy the condition for rated probability of clipping. This process is more complicated than the previous one, and requires the combined use of equations 23(A), 23(B), and Fig. 5. The steps in the solution are as follows:

1. Values for N are assumed, and corresponding values for K_2 are computed from equation 23(B).
2. Values of K_1 corresponding to the values of K_2 in step 1 are found from Fig. 5.
3. Equation 23(A) is rearranged to yield

$$\sigma_l=\frac{E'_{bb}}{K_1N\sqrt{Z_n^2-R_n^2}} \qquad (27)$$

The known values of K_1 and N are then used to determine corresponding values of σ_l.

The graph of σ_l versus N may then be plotted. The shape of the typical curve resulting from the previous three steps is shown also in Fig. 6 and is labelled B. The points in the shaded area above curve B yield values for the probability of clipping which exceed the specified value. The shape of curve B in Fig. 6 can also be described by reference to equations 23(B) and 27 and also Fig. 5.

As N becomes very large K_2 approaches a fixed lower limit:

$$\lim_{N\to\infty} K_2 = \frac{R_n}{\sqrt{Z_n^2 - R_n^2}} \qquad (28)$$

For the specified probability of clipping, K_1 approaches a limit given by Fig. 5. From equation 27, σ_t and N are inversely related for high values of N, because K_1 approaches a constant value. This corresponds to a negative unity slope on logarithmic co-ordinates. As N decreases the magnitude of the slope of curve B in Fig. 6 decreases because K_1 increases in equation 27.

The intersection of curve A and curve B in Fig. 6 yields the maximum value of the rms load current obtainable from the amplifier without exceeding the rated plate dissipation of the power triodes or the specified probability of clipping the output signal. The corresponding value of N is the optimum turns ratio for the output transformer.

Conclusions

The evalution of the performance of push-pull triode power amplifiers in class B operation with random signals has been shown to be based on two reasonable limitations. The average plate power dissipation limitation is exactly the same as that for sinusoidal signals. The limitation involving the amount of clipping or of attempted positive grid operation is roughly comparable to the limitation imposed by the clipping of sinusoidal signals due to grid current. Thus the basic ideas presented in this paper are not really new. However, the application of these ideas for random signals is somewhat more complicated than the application for sinusoidal signals.

Although this paper specifically covers the analysis of amplifiers in which the operation is limited to the negative grid region, the results are not limited in this respect.

It is possible to analyze power amplifiers operating partially in the positive grid region, if the boundaries of the allowable region of operation can be approximated by straight lines as shown in Fig. 3 and given by equation 16. The amplifier limitation then becomes one of grid power dissipation or of available power from the driver stage instead of clipping of the signal due to the flow of grid current.

A Stable Direct-Coupled Transistor Servo Preamplifier

ALBERT N. DeSAUTELS
ASSOCIATE MEMBER AIEE

Synopsis: In the designer approach to transistor servo-amplifier design, only limited consideration has been given to direct coupling. This is particularly true in applications involving operation over a wide temperature range. This paper discusses design and performance relationships and d-c stability considerations for a 2-stage direct-coupled preamplifier capable of d-c operating-point stability and high gain at temperatures in excess of 125 C (degrees centigrade).

In the conventional design of preamplifiers for servo applications, the engineer considers three types of coupling: transformer coupling, R/C coupling, and direct coupling.

In the comparison of the three types shown in Fig. 1, it is apparent that direct coupling has definite merit in miniaturization and economy. However, characteristics of interchanging transistors have generally led circuit designers to give only limited consideration to direct coupling.

Any variation in the d-c conditions of one stage of the conventional direct-coupled amplifier of Fig. 1 creates appreciable interaction with the other stage. This effect can be remedied to a certain extent by introducing considerable d-c degeneration in the emitter circuit. This is done by making the emitter circuit d-c resistance large compared to the collector circuit resistance. Thus, as the collector current increases with temperature increase, this current increase will show up more effectively as an increase in voltage potential at the emitter. With the base voltage fixed, an increase in potential on the emitter will reduce the emitter to base voltage and thus reduce the collector current. The result is a form of temperature compensation that performs fairly well.

However, the problem of interchangeability still exists. If all transistors had the same characteristics, they could be freely interchanged. Since this is not the case, to achieve a-c gain and d-c bias stability with interchanging transistors would require careful selection of transistors, additional stabilizing networks, etc., which, in many applications, is just not practical.

Limitations are also imposed by the use of the tantalum by-pass capacitors due to the temperature characteristics of the capacitors. At low temperatures a-c series resistance of the tantalum increases exponentially and presents a very significant degenerative effect.

A Simplified Direct-Coupled Circuit

A circuit which emphasizes to a high degree the desirable characteristics of small size, simplicity, and economy associated with direct coupling while still achieving excellent a-c stability is

Paper 58-1238, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted February 28, 1958; made available for printing September 18, 1958.

Albert N. DeSautels is with Minneapolis-Honeywell Regulator Company, Minneapolis, Minn.

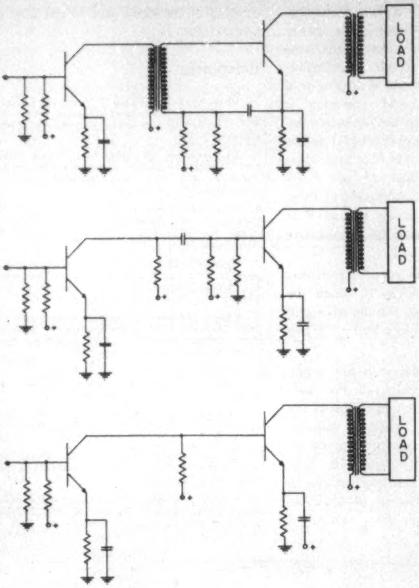

Fig. 1 (left). Conventional transistor preamplifiers

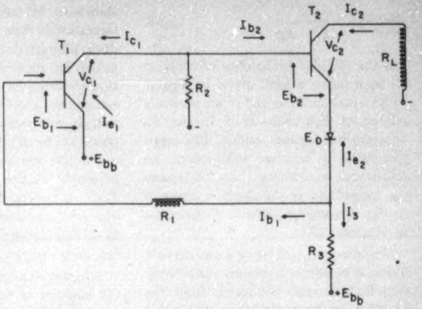

Fig. 3 (above right). Design analysis of direct-coupled preamplifier

shown in Fig. 2. This circuit uses a form of d-c feedback to achieve d-c stability.

Note the simplicity of the design. There are no tantalum capacitors and fewer components, yet this preamplifier is d-c stable with interchanging transistors and is capable of providing stable gain with silicon transistors to temperatures in excess of 125 C.

The theory of stabilization and bias is straightforward. The Zener diode, D_1, utilizes reverse diode characteristics to provide a constant emitter voltage for the second stage, T_2. This diode also determines the d-c collector voltage for the first stage, T_1. The d-c voltage drop across R_1 acts as a generator to provide bias current for T_1. The voltage drop across R_1 establishes the base bias voltage for T_2. When interchanging transistors with slightly different d-c characteristics or when collector currents increase with higher temperature, the circuit should automatically stabilize itself.

If I_{c_1} increases with temperature rise, the voltage drop across R_2 will rise. This means the base voltage of T_2 will decrease with respect to ground. Since emitter voltage of T_2 is constant (due to Zener diode), decrease in base voltage will tend to decrease T_2 collector current. Thus, the drop across R_1 will decrease, tending to reduce the base bias current for T_1 and thus reduce I_{c_1}. The same theory applies for increase in I_{c_2}.

This d-c stability is obtained by means of a tight d-c feedback loop around the two stages. This is provided by L_1 which has low d-c resistance but high a-c impedance. Therefore, there is tight d-c coupling, but practically no a-c feedback.

General Design Relationships

General design equations can be established which will relate component values to power source amplitude and d-c operating points.

From Fig. 3, the following relations are observed:

$$I_{b_1}+I_{c_1}+I_{e_1}=0 \tag{1}$$

$$I_{b_2}+I_{c_2}+I_{e_2}=0 \tag{2}$$

$$I_{b_1}+I_3+I_{e_2}=0 \tag{3}$$

$$I_{b_2}=\frac{I_{c_2}}{\beta_2},\ I_{b_1}=\frac{I_{c_1}}{\beta_1} \tag{4}$$

where β_1 and β_2 are common emitter current gains of T_1 and T_2, respectively.

Taking voltage loop sums and considering all voltages and currents as absolute values:

$$E_{bb}=V_{c_1}+R_2(I_{c_1}+I_{b_2}) \tag{5}$$

$$E_{bb}=I_3R_3+E_D+V_{c_2}+I_{c_2}R_L \tag{6}$$

$$E_{bb}=I_3R_3+E_D+E_{b_2}+R_2(I_{c_1}+I_{b_2}) \tag{7}$$

Solving equations 1 through 4 for I_3,

$$I_3=\frac{I_{c_2}}{\beta_2}+I_{c_2}-\frac{I_{c_1}}{\beta_1} \tag{8}$$

Inserting equation 8 in equation 6 and solving for R_3,

$$R_3=\frac{E_{bb}-E_D-V_{c_2}-I_{c_2}R_L}{I_{c_2}+\frac{I_{c_2}}{\beta_2}-\frac{I_{c_1}}{\beta_1}} \tag{9}$$

From Fig. 3,

$$I_3R_3=I_{b_1}R+E_{b_1} \tag{10}$$

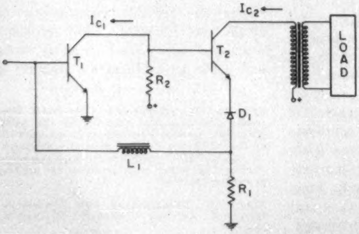

Fig. 2. The d-c stable direct-coupled amplifier

Vol,
Pt. 1
195

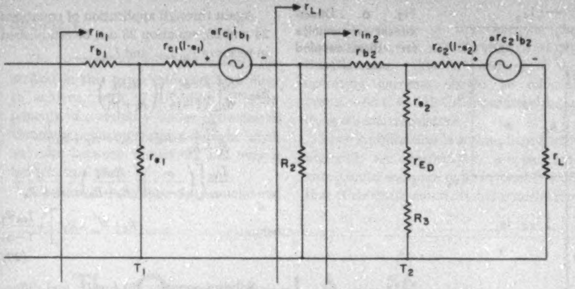

Fig. 4. Equivalent circuit for 2-stage direct-coupled preamplifier

Solving equation 10 for R_1 and submitting equation 8,

$$R_1=\frac{R_3\left(\frac{I_{c_2}}{\beta_2}+I_{c_2}-\frac{I_{c_1}}{\beta_1}\right)-E_{b_1}}{\frac{I_{c_1}}{\beta_1}} \tag{11}$$

From equations 5 and 4,

$$R_2=\frac{E_{bb}-V_{c_1}}{I_{c_1}+\frac{I_{c_2}}{\beta_2}} \tag{12}$$

From Fig. 3,

$$V_{c_1}=E_{b_2}+E_D+I_{b_1}R_1+E_{b_1} \tag{13}$$

Assuming $E_{b_2}=E_{b_1}$,

$$V_{c_1}=2E_{b_1}+E_D+I_{b_1}R_1 \tag{14}$$

Solving equation 14 for E_D and applying equation 4,

$$E_D=V_{c_1}-2E_{b_1}-\frac{I_{c_1}}{\beta_1}R_1 \tag{15}$$

For practical values of R_1, the right-hand term of equation 15 is negligible compared to the other voltages and equation 15 simplifies to

$$E_D\cong V_{c_1}-2E_{b_1} \tag{16}$$

DESIGN SUMMARY

Knowing V_{c_1}, I_{c_1}, V_{c_2}, I_{c_2}, E_{bb}, α_1, α_2, and R_L (d-c load resistance), component values for either *p-n-p* or *n-p-n* 2-stage direct-coupled amplifiers can be calculated from the following relationships using absolute values for current and voltage:

$$E_D=V_{c_1}-2E_{b_1} \tag{16}$$

$$R_3=\frac{E_{bb}-E_D-V_{c_2}-I_{c_2}R_L}{I_{c_2}+\frac{I_{c_2}}{\beta_2}-\frac{I_{c_1}}{\beta_1}} \tag{9}$$

$$R_1=\frac{R_3\left(I_{c_2}+\frac{I_{c_2}}{\beta_2}-\frac{I_{c_1}}{\beta_1}\right)-E_{b_1}}{\frac{I_{c_1}}{\beta_1}} \tag{11}$$

$$R_2=\frac{E_{bb}-V_{c_1}}{I_{c_1}+\frac{I_{c_2}}{\beta_2}} \tag{12}$$

Performance

In terms of a-c performance, the equivalent circuit would appear as shown in Fig. 4. Two-stage relationships for performance analysis can be established from this circuit in combined terms. However, the resulting equations are too complex for practical usage. It is more convenient to make a stage by stage analysis using established amplifier stage relationships.

Through use of

$$A_v=\frac{\alpha r_c r_L}{r_c[r_e+r_b(1-\alpha)]+r_L(r_e+r_b)} \tag{17}$$

and

$$A_i=\frac{\alpha}{1-\alpha+\frac{r_L}{r_c}} \tag{18}$$

for a known a-c load impedance, r_L, and using average small signal parameters associated with the selected operating points, the voltage and current gain of T_2 is calculated. Then r_{in_2} is calculated from

$$r_{in_2}=(r_{b_2}+r_{e_2}+r_{ED}+R_3)\left[\frac{r_{c_2}+r_L}{r_{c_2}(1-\alpha_2)+r_L}\right] \tag{19}$$

The second-stage input impedance, r_{in_2}, in parallel with R_2 provides the first stage load impedance, r_L. With r_{L_1} known equations 17 and 18 can again be used applying small signal parameters associated with T_1. The amplifier input impedance, r_{in_1}, would be obtained from

$$r_{in_1}=r_{b_1}+\frac{r_{e_1}}{1-\alpha_1} \tag{20}$$

Typical performance figures for this amplifier would be

TEMPERATURE PERFORMANCE

The graph of Fig. 5 presents comparative amplifier response at 25 C, 125 C, and −55 C as calculated for typical transistors. Stability of performance over the temperature range is indicated.

Table I presents comparative d-c collector current values as determined for the temperature extremes. Less than 15% variation in direct current from room temperature to temperature extremes is indicated.

Some D-C Stability Considerations

Direct-current stability of the direct-coupled circuit is especially important where a wide temperature range and interchangeability requirement exists. Analysis of the d-c biasing network will provide a means for measuring circuit stability. Since perhaps the greatest contributor to d-c operating point change with temperature is the change due to inverse saturation current, I_{co}, temperature characteristics, it is appropriate to associate the stability of I_{c_1} and I_{c_2} in Fig. 6 with the I_{co} change in both T_1 and T_2.

The following three assumptions are made:

1. V_c, collector to emitter voltage, has a negligible effect on collector current.
2. Alpha is constant over the operating range.
3. E_{be}, the base-emitter voltage, is negligible. In the case of germanium, it is approximately 0.1 volt; for silicon, in the order of 0.6 volt.

From Fig. 6, the following relationships are evident:

$$I_{e_1}=I_{b_1}+I_{c_1} \tag{21}$$

$$I_{e_2}=I_{b_2}+I_{c_2} \tag{22}$$

$$E_{bb}=(I_{c_1}+I_{b_1})R_2+I_{e_2}(R_D-R_3)-I_{b_1}R_3 \tag{23}$$

Since

$$\alpha I_e=I_c+I_{co}$$

or

$$I_e=\frac{I_c}{\alpha}-\frac{I_{co}}{\alpha} \tag{24}$$

then

$$I_b=I_c\frac{(1-\alpha)}{\alpha}-\frac{I_{co}}{\alpha} \tag{25}$$

Through application of equations 24 and 25, equation 23 can be established in terms of I_{c_1}, I_{co_1}, and I_{co_2},

$$E_{bb}=I_{c_1}\left[R_2-R_3\left(\frac{1-\alpha_1}{\alpha_1}\right)+(R_1+R_3)\times\left(\frac{1-\alpha_1}{\alpha_1}\right)\frac{R_2-R_2\alpha_2+R_D+R_3}{R_3}\right]+I_{co_1}\left[\frac{R_3}{\alpha_1}-\left(\frac{R_1+R_3}{\alpha_1}\right)\times\left(\frac{R_2-R_2\alpha_2+R_D+R_3}{R_3}\right)\right]-I_{co_2}R_2 \tag{26}$$

Solving equation 26 for I_{c_1} and differentiating, first with respect to I_{co_1} and then with respect to I_{co_2},

$$\frac{\partial I_{c_1}}{\partial I_{co_1}}=-\cfrac{1}{\cfrac{\alpha_1R_3R_2}{R_3^2-(R_1+R_3)(R_2-R_2\alpha_2+R_D+R_3)}-(1-\alpha_1)} \tag{27}$$

$$\frac{\partial I_{c_1}}{\partial I_{co_2}}=\cfrac{R_2}{R_2-R_3\left(\cfrac{1-\alpha_1}{\alpha_1}\right)+\cfrac{(R_1+R_3)(1-\alpha_1)(R_2-R_2\alpha_2+R_D+R_3)}{\alpha_1R_3}} \tag{28}$$

Again through application of equations 24 and 25, equation 23 can be established in terms of I_{c_2}, I_{co_1}, and I_{co_2},

$$E_{bb}=\frac{I_{c_2}}{\alpha_2}\left[\left(\frac{\alpha_1}{1-\alpha_1}\right)\left(\frac{R_3R_2}{R_1+R_3}\right)-\frac{R_3^2}{R_1+R_3}+R_2(1-\alpha_2)+R_D+R_3\right]-\frac{I_{co_2}}{\alpha_2}\left[\left(\frac{\alpha_1}{1-\alpha_1}\right)\left(\frac{R_3R_2}{R_1+R_3}\right)-\frac{R_3^2}{R_1+R_3}+(R_2+R_D+R_3)\right]+\frac{I_{co_1}R_3}{1-\alpha_1} \tag{29}$$

Solving equation 29 for I_{c_2} and differentiating, first with respect to I_{co_2} and then with respect to I_{co_1},

$$\frac{\partial I_{c_2}}{\partial I_{co_2}}=\frac{\left[\left(\frac{\alpha_1}{1-\alpha_1}\right)\left(\frac{R_3R_2}{R_1+R_3}\right)-\frac{R_3^2}{R_1+R_3}+(R_2+R_D+R_3)\right]}{\left[\left(\frac{\alpha_1}{1-\alpha_1}\right)\left(\frac{R_3R_2}{R_1+R_3}\right)-\frac{R_3^2}{R_1+R_3}+R_2(1-\alpha_2)+R_D+R_3\right]} \tag{30}$$

$$\frac{\partial I_{c_2}}{\partial I_{co_1}}=\frac{R_c}{\frac{1-\alpha_1}{\alpha_2}\left[\left(\frac{\alpha_1}{1-\alpha_1}\right)\left(\frac{R_3R_2}{R_1+R_3}\right)-\frac{R_3^2}{R_1+R_3}+R_2(1-\alpha_2)+R_D+R_3\right]} \tag{31}$$

From the four differential expressions, equations 27, 28, 30, and 31, the change in I_{c_1} can be expressed as a function of I_{co} change,

$$dI_{c_1}=\frac{\partial I_{c_1}}{\partial I_{co_1}}\,dI_{co_1}+\frac{\partial I_{c_1}}{\partial I_{co_2}}\,dI_{co_2} \tag{32}$$

and the change in I_{c_2} can be expressed in a similar fashion.

$$dI_{c_2}=\frac{\partial I_{c_2}}{\partial I_{co_1}}\,dI_{co_1}+\frac{\partial I_{c_2}}{\partial I_{co_2}}\,dI_{co_2} \tag{33}$$

If it is assumed that the I_{co} temperature characteristic is the same for both transistors, then $dI_{co_1}=dI_{co_2}$. The partial expressions of equations 32 and 33 may therefore be combined to produce stability factors relating the change in I_{c_1} and I_{c_2} to I_{co} change:

$$\frac{dI_{c_1}}{dI_{co}}=S_1=\frac{\partial I_{c_1}}{\partial I_{co_1}}+\frac{\partial I_{c_1}}{\partial I_{co_2}} \tag{34}$$

$$\frac{dI_{c_1}}{dI_{co}}=S_2=\frac{\partial I_{c_2}}{\partial I_{co_1}}+\frac{\partial I_{c_2}}{\partial I_{co_2}} \tag{35}$$

Ideally, S_1 and S_2 should approach zero. That is, the change in I_c due to one I_{co} will be cancelled by an opposing change in I_c due to the other I_{co}. Practically, in the amplifier discussed in this paper, S_1 is about 1 and S_2 is about 10.

Summary

The 2-stage transistor preamplifier described in this paper indicates an ability to achieve, with a minimum of components, d-c stability under extremes of transistor characteristics changes such as occur between transistors and over a temperature range.

Adequate d-c stability can be achieved under conditions of interchanging the transistors having a beta range of nearly three to one. Effective control of d-c operating currents should be effected over a −55 C to 125 C temperature range using silicon transistors.

Since stabilization is accomplished with negligible a-c degeneration, a-c performance should compare quite favorably with that of the more conventional transformer or *R/C* coupled preamplifiers. Design and stability factor relationships are applicable to *p-n-p* as well as *n-p-n* types of transistors.

The Operational Amplifier as a Laboratory Tool

PAUL E. PFEIFFER
ASSOCIATE MEMBER AIEE

THE "operational amplifier" as it is usually referred to in computer terminology has proved its versatility and usefulness as the backbone of modern electronic differential analyzers. In a rapidly increasing number of engineering offices, schools, and laboratories, these devices are available either in small computing installations or as separate plug-in units. It is the purpose of this paper to describe briefly their operation and to show how their usefulness may be extended beyond the usual computing applications. The applications described are suggested by a point of view which is certainly not new, but which does not seem to have been exploited to its fullest extent.

Characteristics and Function of Operational Amplifiers

The operational amplifier is normally used in a feedback arrangement as shown in Fig. 1. The amplifier itself is a high-gain d-c amplifier having a negative gain and a reasonably small output impedance, so that normal loads do not appreciably affect the voltage gain. The input to the amplifier at the junction of the input and feedback paths is known as the summing point. The voltage at this point will be referred to as the summing point voltage, and the current entering the amplifier will be referred to as the summing point current. These are designated by e_s and i_s in Fig. 1. It should be noted that all voltages referred to are potentials with respect to a fixed reference level taken as zero. This is often referred to as the signal ground.

Table I lists ideal characteristics of the operational amplifier and typical values which may be expected in actual equipment. From the characteristics listed in this table, it is apparent that the summing point potential cannot exceed a few millivolts. Currents entering the summing point must add to equal the summing point current, which is of the order of 0.01 μa (microamperes) to 100 $\mu\mu$a. Input and output voltages act through transmission elements, which may be quite nonlinear in some cases, to produce currents and voltages at the summing point. Under the assumption of stable operation within the linear range of the amplifier, the function of the amplifier may be idealized as follows. The output voltage adjusts automatically to maintain, to a high degree of approximation, the two conditions: 1. Zero net summing point current (current balance condition). 2. Zero summing point voltage.

This simplified view of the function of the operational amplifier aids the comprehension of known circuits and helps to visualize new possiblities. Once a circuit is conceived on the basis of the approximation, its operation may be studied with more precision by careful analysis which takes into account such factors as finite gain, drift, output impedance, stability considerations, etc. Often, however, it is sufficient to make simple approximate calculations based on the actual parameters to determine bounds on errors due to departure from the ideal. For example, if it is known that the summing point is less than 1,000 $\mu\mu$a, then the current balance must be within this figure. For many applications, this error is immediately seen to be entirely negligible. Or if it is known that output voltage will not exceed 20 volts, then an amplifier voltage gain of 10^4 insures that the summing point voltage is less than 2 millivolts in magnitude. This may be sufficient information to show that the assumption of zero summing point voltage leads to negligible errors.

Some Useful Operations Performed by Operational Amplifiers

Three useful functions performed by the operational amplifier are the basis of

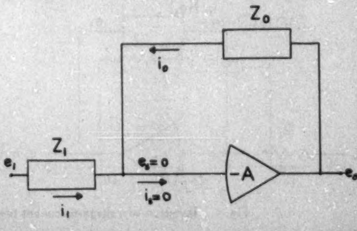

Fig. 1. Usual feedback configuration for operational amplifier

---

Paper 58-1198, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted June 16, 1958; made available for printing August 12, 1958.

Paul E. Pfeiffer is with The Rice Institute, Houston, Tex.

The author is grateful to a number of students who have tested various of the schemes described herein; especially to W. R. Peters, electronics technician in the Electrical Engineering Department, Rice Institute, for suggesting the resistance comparison scheme and putting into practice some of the ideas reported in this paper.

Table I. Operational Amplifier Characteristics

Items	Values		
	Ideal	Practical Range	
Voltage gain*	minus infinity	-10^4	-10^8
Input current	0	10^{-8}	10^{-11} amperes
Output impedance	0	300 ohms	100 ohms
Drift (referred to input)	0	2 millivolts	100 μvolts
Maximum load current		2 milliamperes	15 milliamperes
Maximum output voltage		±50 volts	±125 volts
Maximum summing point voltage	0	10 millivolts	1 millivolt

* With auxiliary chopper stabilizing amplifiers, d-c gain may be in excess of 10^7, giving summing point voltages at d-c of the order of 10^{-6} volts.

most of the techniques described in this paper:

1. Current measuring; see Fig. 2.
2. Current controlling; see Fig. 3.
3. Feedback function inversion; see Fig. 4.

These functions are, of course, simply ways of utilizing the inherent operation of the amplifier and feedback configuration, and are therefore closely related.

The current-measuring function is readily apparent from the requirements of the current balance condition, which requires that the current entering the summing point be equal to the current leaving by the feedback resistor path. This requires that for the circuit of Fig. 2 the relation $e_0=-i_1R_0$ must hold. Within the current-handling limits of the amplifier, this condition must be met regardless of load impedance. Hence a low-impedance voltmeter of a precision laboratory type may be used for current indication. It should be noted that the current is measured at a point essentially at signal ground potential. This has the advantage of producing small voltage drops in the current path. However, the current measured must be current to ground. If R_0 is sufficiently high, extremely small currents down to the order of 100 μμa may be indicated.

The measurement of extremely small currents, however, may be subject to a considerable number of errors due to drift voltages. Analysis shows this to be especially serious if the source impedance is small compared to the feedback resistor R_0. This situation, however, is not likely to occur, as an example will show. Suppose it is desired that a current of the order of 10^{-8} amperes be measured. A feedback resistor R_0 of 10 megohms would give a drop of 0.1 volt. This means that the source impedance would also have to be at least 10 megohms if the source voltage were as much at 0.1 volt. In the case of very low source voltages, much more detailed procedure and analysis are necessary to account for significant factors. In these cases, however, any measurement techniques are likely to be difficult.

The current-controlling function is obtained by making the input element a resistor R_1, and putting the device to be controlled in the feedback path, as in Fig. 3. Input current i_1 is very nearly proportional to input voltage e_1. Variations of the current i_1 from the value e_1/R_1 are due to the summing point voltage required to produce the necessary amplifier output voltage e_0. The magnitude of the i_1 variations from the desired amount are approximately e_0/AR_1. It is, of course, assumed that the system is stable. Generally this requires that an increase in the output voltage produces an increase in feedback current.

The feedback function inversion operation is a special case of the current control operation. Two cases are indicated in Fig. 4. In Fig. 4(A) it is assumed that the feedback element is such that its output current $i_0=f(e_0)$. If an inverse function exists, then

$$e_0=f^{-1}(i_0)=f^{-1}(-e_1/R_1) \tag{1}$$

If the feedback element is essentially a voltage transfer element, it may be converted to a current output element by

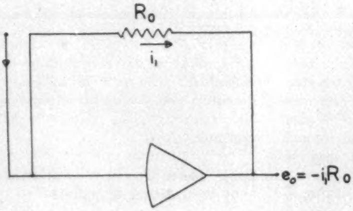

Fig. 2 (left). Operational amplifier as current-measuring device

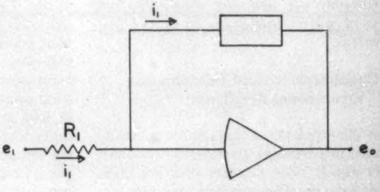

Fig. 3 (right). Operational amplifier as current-controlling device

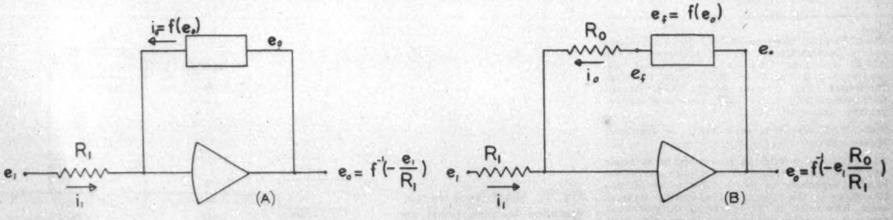

Fig. 4. Inversion of voltage-to-current transmission element and of voltage-to-voltage transmission element

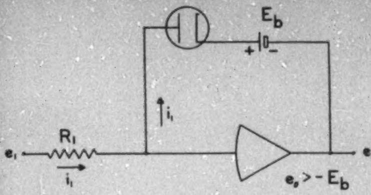

Fig. 5 (left). Logarithmic amplifier

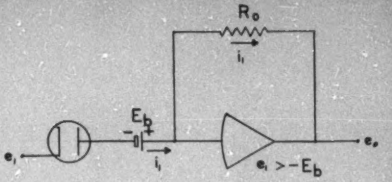

Fig. 6 (right). Exponential amplifier

adding a resistor R_0. Under the usual assumption of negligible summing point voltage, $i_0=e_f/R_0$. If $e_f=f(e_0)$, then

$$e_0=f^{-1}(-e_1R_0/R_1) \tag{2}$$

Applications

The following examples serve to illustrate the functions just described. Also it is believed that they are of interest in themselves. They have been employed in a number of applications in the laboratory.

LOGARITHMIC AMPLIFIER

The logarithmic amplifier diagrammed in Fig. 5 may be considered as an example of either current control or feedback function inversion.

If a thermionic vacuum diode is operated in the negative plate potential region, the current is an exponential function of the plate potential. This relationship may be quite precise over several decades of current range. If a biased diode is used as a feedback element, as shown in Fig. 5, the output voltage is proportional to the logarithm of the input voltage for several decades of the latter. The current balance equation for this circuit becomes

$$\begin{aligned} e_1/R_1 &= i_0 \exp\left[-\alpha(e_0+E_b)\right] \\ &= I_b \exp(-\alpha e_0) \end{aligned} \tag{3}$$

where $I_b=i_0\exp(-\alpha E_b)$. Equation 3 may be rewritten

$$\exp(-\alpha e_0)=e_1/(I_bR_1)=e_1/e_{1b} \tag{4}$$

Taking logarithms leads to the result

$$\begin{aligned} e_0 &= -(1/\alpha)\ln(e_1/e_{1b}) \\ &= -K_\alpha \log_{10}(e_1/e_{1b}) \end{aligned} \tag{5}$$

In equations 4 and 5, e_{1b} is the value of e_1 required to make e_0 equal to zero. The factor $K_\alpha=2.3026/\alpha$ is in volts per decade of current in the diode, or volts output per decade of input voltage change.

It is obvious that the logarithmic range cannot extend to zero since log x becomes negatively infinite as x goes to zero. Leakage resistance in the diode, amplifier saturation, etc., serve to provide the inevitable physical limits. It is also easily shown that the dynamic resistance of the diode becomes quite high for very small currents. Thus with small e_1 the amplifier operates with very small feedback and its sensitivity to stray pickup, internal noise, etc., becomes quite high. The gain in these regions may be limited at the expense of the range of logarithmic behavior by shunting the diode with a very high resistance.

The circuit has been used successfully with a pair of diodes in opposite directions to give logarithmic compression of a-c signals. It has also been used in a special-purpose computer involving several logarithmic and antilogarithmic amplifiers, with good over-all accuracy.[1]

AN EXPONENTIAL AMPLIFIER

If the biased diode utilized in the logarithmic amplifier is used as the input element rather than the feedback element, the resulting system provides an exponential relation between output and input voltage. The basic diode equation, Fig. 6, is

$$\begin{aligned} i_1 &= -i_0 \exp\left[-\alpha(e_1+E_b)\right] \\ &= -I_b \exp(-\alpha e_1) \end{aligned} \tag{6}$$

This results in output voltage e_0 given by

$$e_0=-i_1R_0=E_0\exp(-\alpha e_1),\ \text{for } e_1>-E_b \tag{7}$$

Here $E_0=I_bR_0$ is the output voltage when e_1 is zero.

By reversing the diode, the system may be used to handle positive voltages. The behavior is indicated by making appropriate sign changes in equations 6 and 7. Within the appropriate voltage ranges, good exponential behavior for two to three decades of output voltage is possible.

INVERSION OF VOLTAGE TRANSFER FUNCTIONS

The circuit of Fig. 7 shows a simple arrangement for inversion of a voltage transfer function. If $G(s)$ is the voltage transfer function $E_f(s)/E_0(s)$, the current balance condition leads directly to the result

$$\frac{E_0(s)}{E_1(s)}=\frac{-R_0}{R_1G(s)} \tag{8}$$

It should be noted that only minimum phase transfer functions are stable when inverted.

These techniques have been utilized in the study of certain unstable systems.[2] Unstable systems of known transfer functions are obtained by inverting nonminimum phase transfer functions. These in turn are stabilized by putting them in an appropriate feedback loop. The behavior of the unstable system is then studied by driving the outer loop and measuring within the loop.

MEASUREMENT OF VACUUM TUBE PARAMETERS

The use of vacuum tubes at low voltage and currents is receiving considerable attention.[3] Published data on tubes for such operation are limited and in many cases nonexistent. The measuring and controlling function of the amplifier plus its very small grid or summing point swing may be utilized to provide simple measurement techniques. Figs. 8 and 9 contain circuits for ready measurement of the basic parameters of a triode.

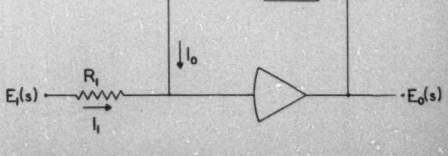

Fig. 7. Inversion of voltage transfer function

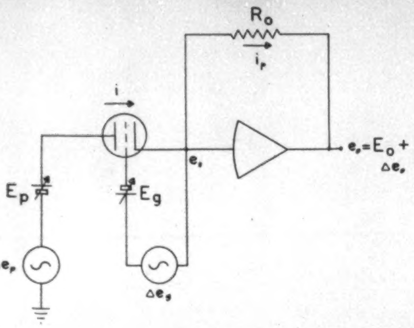

Fig. 8. Circuit for measuring transconductance and plate resistance

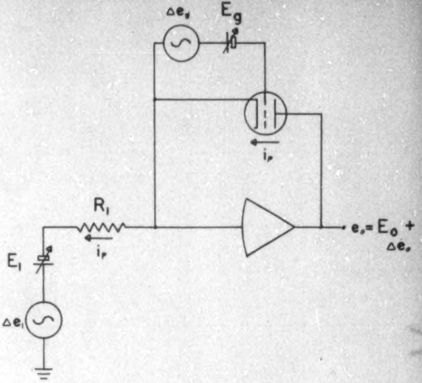

Fig. 9. Circuit for measuring amplification factor and plate resistance

Vol
Pt.
195

The circuit of Fig. 8 may be used to determine the transconductance g_m and the plate resistance r_p; the circuit of Fig. 9 yields measurements of amplification factor μ and the plate resistance r_p. Of course, any two of these parameters give the third by their well-known relationship $\mu = r_p g_m$.

Measurement of Transconductance

By definition

$$g_m = (\Delta i_p/\Delta e_g) \tag{9}$$

with e_p constant. In the circuit of Fig. 8 the plate voltage E_p and the grid bias E_g are fixed at the desired values. Measurement of the d-c component E_0 of the output voltage e_0 gives plate current I_p according to the relation $I_p = -(E_0/R_0)$.. Hence, static characteristics of the tube are readily obtained. An a-c component of grid voltage Δe_g is added in series with the bias voltage. Because of the negligible summing point voltage swing, the variation of E_p thus produced is negligible. Hence

$$g_m = -\Delta e_0/(\Delta e_g R_0) \tag{10}$$

By making $R_0 \Delta e_g$ some convenient power of 10, readings of Δe_0 are equal to $-g_m$ in corresponding units. For example, if R_0 is 0.1 megohm and Δe_g is 0.01 volt, then $-\Delta e_0$ is equal to g_m in thousands of micromhos. For convenience, Δe_g is made a low frequency sine wave so that the static components are read with d-c voltmeters and the changing portions are read on a-c instruments.

For many tubes, the circuit of Fig. 8 may be simplified by returning the bias voltage to ground rather than to the cathode. In this case, the voltage Δe_g differs from the applied voltage by the swing Δe_s of the summing point voltage. Often this is quite negligible. Also, the plate voltage differs from the applied voltage by Δe_s. This can nearly always be neglected. If the effect of Δe_s on plate voltage is neglected, the true value of g_m is obtained by multiplying the apparent values given in equation 10 by the factor $(1-E_A)$ where E_A is given by

$$E_A = 1/(1+A/R_0 g_m) \doteq R_0 g_m/A \tag{11}$$

Measurement of Amplification Factor

By definition

$$\mu = -(\Delta e_p/\Delta e_g) \tag{12}$$

with i_p constant. The circuit of Fig. 9 controls i_p and keeps it constant at the value $-E_1/R_1$. The potential Δe_1 is kept zero. The grid bias voltage E_g is set at the desired value and the d-c component E_0 of the output voltage e_0 is the plate voltage. Note that negative E_1 makes for positive E_p as required physically. Measurement of μ is a straightforward voltage ratio measurement as indicated in equation 12.

As in the circuit of Fig. 8, the grid voltage may be returned to the ground rather than to the summing point. Also, as in the previous case, the true value of μ is obtained by multiplying the apparent value by $(1-E_A)$ with E_A given in equation 11. This may be rewritten

$$E_A = \mu R_0/A r_p \tag{13}$$

Thus if R_0 is of the same order of magnitude as the plate resistance r_p, the error is approximately μ/A. For $A = 10^4$, a value of μ of 100 would be measured wth an error of about 1%, and in any case the error would tend to increase with μ.

Measurement of Plate Resistance

By definition

$$r_p = (\Delta e_p/\Delta i_p) \tag{14}$$

with e_g constant. Two possibilities pre-

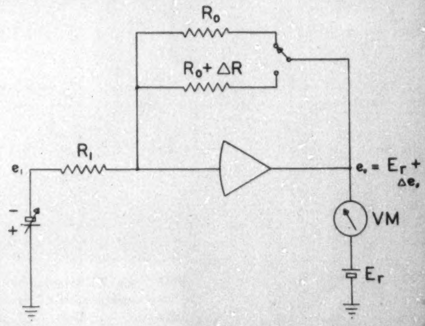

Fig. 10. Resistance comparison scheme

sent themselves. One is to make Δe_p the driving function and measure Δi_p. In the circuit of Fig. 8 this is accomplished in a straightforward manner. Thus

$$r_p = -(\Delta e_p/\Delta e_0)R_0 \tag{15}$$

Possibilities for direct reading by suitable choice of R_0 and Δe_0 are apparent. As in the case of the g_m measurements, static operating conditions are indicated.

If the circuit of Fig. 9 is used, Δi_p is made the driving function by controlling Δe_1 (with Δe_g held at zero). In this case

$$r_p = -(\Delta e_0/\Delta e_1)R_1 \tag{16}$$

For measurement of plate resistance, returning the grid voltage to ground will produce errors similar to those in the other parameters. Generally these errors are quite negligible for practical purposes and the simpler arrangement may be used satisfactorily.

It should be apparent that similar techniques can be used with transistors. This in fact has been done by one of the author's students.[4]

A D-C Resistance Comparison Circuit

A very simple resistance comparison scheme has been suggested by W. R. Peters. It works quite well for high resistances, up to possibly 100 megohms. For high resistances, oridinary bridges become quite insensitive, whereas this system maintains its null sensitivity. Also, in this system, the null indication is linear with respect to resistance variation. A simplified configuration is shown in Fig. 10. The operation is as follows: Suppose the resistance R_0 is taken as standard. Input voltage e_1 is adjusted until output voltage e_0 is equal to the reference or pedestal voltage E_r, as indicated by zero reading on the null voltmeter. Comparison resistor $R_0+\Delta R$ is then switched into the feedback path. The voltage equations in the two cases are respectively

$$E_r = -e_1(R_0/R_1) \tag{17}$$

and

$$E_r+\Delta e_0 = -e_1[(R_0+\Delta R)/R_1] \tag{18}$$

A little algebra shows that these relations imply

$$(\Delta e_0/E_r) = (\Delta R/R_0) \tag{19}$$

Notice that R_1 does not appear in the final expression. Also, the null voltage reading Δe_0 gives a direct linear measure of the variation of the comparison resistance from the standard. Care should be taken to protect a sensitive voltmeter during the switching instant, since momentarily the output is likely to vary considerably from E_r. This can be handled by proper switching, if desired.

Conclusions

The versatility of the operational amplifier is such that its usefulness is not limited to the usual computing applications, manifold and important as they are. The laboratory techniques described in this paper represent the more useful and interesting of the ideas which have been utilized by the author and his students. They were for the most part visualized in terms of the three basic operations of current measurement, current control, and feedback function inversion. Specific circuits, once conceived, may be analyzed more exactly by the usual techniques and methods of analysis. It is believed that the list of useful applications can be extended considerably by anyone who understands the basic operations. The principal limit on the applications is probably the current and voltage limitations of the operational amplifiers available.

◆

Discussion

James R. Cox (A. and M. College of Texas, College Station, Tex.): Dr. Pfeiffer's organization of some of the less conventional uses of operational amplifiers should lead to new circuits employing these amplifiers. Several ideas similar to those described in the paper have been used at the A. and M. College of Texas where, however, the circuits have been treated on an individual basis, not by an organized method that would lead logically into new circuits.

The operational amplifier method of measuring tube parameters was found to be convenient and accurate. In the case of current measurements, chopper stabilization of the amplifier was found valuable. In some cases, a microammeter or galvanometer was used in the feedback loop. In this configuration, the amplifier effectively lowers the impedance of the meter to a few ohms. The current is read directly. Also, precision capacitors with low leakage, usually available in analog computers, can be substituted for the feedback resistor. This is convenient for millimicroampere currents when precision resistors of sufficient size are not available. The current is given by

$$i = C\frac{de_0}{dt} \tag{20}$$

or in the case of constant current

$$I = C\frac{\Delta E_0}{\Delta T} \tag{21}$$

The current is found by timing output voltage change with a stop watch.

A chopper stabilized amplifier and microammeter is being used as a voltage detector for a Wheatstone bridge. While its sensitivity compares with that of a galvanometer, it is more rugged, easier to use, and can be mounted on a radio rack panel. In addition, its sensitivity is continuously variable.

Dr. J. R. Biard has used the basic idea of the logarithmic and exponential amplifiers in an electronic multiplier. The multiplier is more versatile than other multipliers since it can raise variables to integral or nonintegral powers as well as multiply two variables. The operator, however, is burdened with a somewhat complicated alignment procedure.

T. N. Whitaker (University of Houston, Houston, Tex.): Dr. Pfeiffer views the operational amplifier as worthy of study in its own right; emphasizes its versatility and shows several noncomputing uses other than the usual one of analog computation. The great significance of this familiar use has tended to distract attention from finding the others. This paper should help restore balance.

It seems appropriate to expand somewhat on the less orthodox uses suggested by the author. Reference 2 of the paper explains the use of operational amplifiers in the experimental study of certain unstable systems. The major emphasis of this earlier paper was on the minimum phase condition, and only incidentally on the use of operational amplifiers. This is a rich vein to work, nonetheless, for it illustrates several different uses of amplifiers as laboratory tools.

It was desired to synthesize a nonminimum-phase system for laboratory demonstration of its unstable nature. Operational amplifiers were used at several steps in this synthesis because of their particular input-output characteristics. Since the non-minimum-phase transfer function may be represented as the tandem sum of a minimum-phase, plus an all-pass transfer function, the synthesis of an all-pass section was deemed necessary. This was accomplished, in part, through the use of a resistance-capacitance phase-shifting network. Instead of using a center-tapped transformer to provide the necessary 180-degree phase difference in the voltages applied to the two ends, an operational amplifier was used to invert the phase at one terminal. This combination simulates a near-perfect center-tapped transformer which has the remarkable characteristic of constant transmission down to zero frequency. Also, this is an application of the inversion of the simplest voltage transfer function, a constant.

Once the phase-lag circuit was synthesized, its transfer function was inverted by use of another amplifier, specifically mentioned in this paper. The resulting system was the system of interest in the study, but it was unstable and, in that form, not amenable to study. It was recognized that this system could be made a part of a larger, stable system by closing an appropriate feedback loop. A third operational amplifier made this possible. This was another noncomputing use of the amplifier, and an example of the fruitfulness of a point of view. The other applications mentioned in the paper illustrate this, too, for they developed only after the characteristics peculiar to the operational amplifier were recognized.

Many other examples could be quoted. The operational amplifier can become a most effective laboratory tool for students well-versed in its use. When students are encouraged to use it to simulate the systems being studied in lecture sessions, further applications often result. Those who have used the operational amplifiers in this manner fully expect the list of noncomputing applications to grow steadily.

H. M. Paynter (Massachusetts Institute of Technology, Cambridge, Mass.): This paper adds substantial lore to the growing body of practical doctrine of feedback instrumentation. Plug-in operational amplifiers are now trustworthy items of laboratory ware.

While the writer concurs enthusiastically with the examples and philosophy contained in the paper, he feels that the reader who is new to the art might appreciate additional references which extend the scope of applications and technique. Thus, he calls attention to the recent writings in the following bibliography as being of interest.

Paul E. Pfeiffer: Each of the discussers has contributed to the aim of the paper as stated in the introduction. It is encouraging to have Mr. Cox refer to the approach as "an organized method that would lead logically into new circuits." The paper began as a survey article for a tutorial session on analog computers. In the process of organizing the material, the author discovered circuits and applications that were new to him at the time. These have contributed to several research projects, one of which is reported briefly in reference 2 of the paper and helpfully elaborated upon by Prof. Whitaker. Mr. Cox describes interesting additions to and variations of the applications reported in the paper, some of which represent his own unpublished work. Prof. Paynter provides a useful list from the rapidly expanding number of papers on various aspects of analog simulation.

Silicon-Controlled Rectifiers from Oxide-Masked Diffused Structures

R. W. ALDRICH
NONMEMBER AIEE

N. HOLONYAK, JR.
NONMEMBER AIEE

THERE is a considerable body of literature on the theoretical and experimental characteristics of 2- and 3-terminal *p-n-p-n* negative resistance switches.[1–4] This paper describes a 2-impurity simultaneous-diffusion process for producing structures in silicon which are suitable for 2- or 3-terminal signal and power *p-n-p-n* switches ("controlled rectifiers"); the properties of the devices produced by this process are discussed in the following.

In a previous paper a mechanism is described by which almost any 4-region device of *p-n-p-n*, *p-n-p-m*, or *n-p-n-m* configuration can be made to exhibit switching action.[3] It is shown that the field resulting from current flow through the interior base regions can (if thermal destruction does not occur first) increase minority carrier transport efficiency (i.e., increase alpha) across one or both base regions until the switching condition $\alpha_{NPN}+\alpha_{PNP}\geqslant 1$ is reached. Switching will not occur only if the sum of the respective emitter efficiencies $\gamma_{NPN}+\gamma_{PNP}$ is less than unity at high currents.

Device Theory and Design

A typical structure and summary of electrical characteristics is shown in Fig. 1. One exterior region, an *n*-type emitter region, is shown grounded. Adjacent to it is a thin (high-alpha) *p*-type base region to which is attached a control electrode. Next to the thin *p*-type base region is a relatively thick *n*-type base region of dimension W_N, resistivity ρ_N, minority carrier (hole) lifetime τ_p, and hole mobility μ_p. Finally there is, adjacent to the thick *n*-type base region, an exterior *p*-type region which acts as an emitter and to which is affixed one of the main current-carrying electrodes of the device. If this region were not present, the device would be a conventional *n-p-n* transistor (of relatively high alpha-α_{NPN}) connected in the grounded emitter configuration.

The expression for the current I through the collector junction between the thick *n* and thin *p* base regions is[3,4]

$$I=\frac{I_{co}'+I_b\cdot\alpha_{NPN}}{1-(\alpha_{NPN}+\alpha_{PNP})} \tag{1}$$

where I_{co} is a saturation current term with some modification due to changes in alphas and due to multiplication,[1] I_b is the control current, α_{NPN} is the electron alpha across the thin *p*-type base region, and α_{PNP} is the hole alphas across the relatively thick *n*-type base region of width W_N. It is obvious that at relatively low currents, where $\alpha_{NPN}\sim 0.7$ to 0.9 and α_{PNP} is negligible, the device behaves

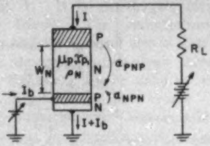

Fig. 1. Current characteristics prior to and at onset of switching of n-p-n-p controlled rectifier (switch)

$$I=\frac{I_{co}'+I_b\cdot\alpha_{NPN}}{1-(\alpha_{NP}+\alpha_{PNP}}$$

$$=\frac{I_{co}'+I_b\cdot\alpha_{NPN}}{(1-\alpha_{NPN})\left(1-\frac{\alpha_{PNP}}{1-\alpha_{NPN}}\right)}$$

$$J_B\sim\frac{W_N}{\mu_p\rho_N\tau_p\ln(1-\alpha_{NPN})^{-1}}$$

$$=\frac{W_N}{\mu_p\rho_N\tau_p\ln\beta_{NPN}'}$$

$$\text{where }\beta'_{NPN}\equiv\frac{1}{1-\alpha_{NPN}}\approx\frac{\alpha_{NPN}}{1-\alpha_{NPN}}\equiv\beta_{NPN}$$

much as a grounded emitter transistor. (The effects of multiplication are not considered; the device is generally biased well below the avalanche voltage of the collector junction. However, by properly defining the alphas to include multiplication, if any, equation 1 is still valid. In 2-terminal operation, on the other hand, avalanche or some other breakdown mechanism is required to produce the relatively high current density necessary to raise the low-voltage alpha sum to unity.) As the control current I_b is increased, both α_{NPN} and α_{PNP} increase until $\alpha_{NPN}+\alpha_{PNP}\geqslant 1$, and the device switches; i.e., the collector junction becomes forward-biased rather than reverse-biased and a total potential of the order of 1 volt exists from end to end across the device.[1-4]

α_{NPN} increases with increased current in the device because of the much-discussed trap and/or generation-recombination processes characteristic of silicon. Since the *n*-type base region is relatively thick, α_{PNP} does not increase sufficiently to produce switching by the aforementioned mechanisms. However, as I_b is increased, and a rather large electron current is caused to flow in the *n*-type base, a field is developed which causes α_{PNP} to increase to the critical value.

A theoretical expression based on a rather ideal model, which includes the effects of the field in the thick *n*-type base region, has previously been derived for the turn-on current, i.e. the load current at which the device switches to a very low forward impedance.[3] An approximate expression for the current density at which switching occurs in low lifetime material ($W_N>>L_p$, the diffusion length) is

$$J_S\sim\frac{W_N}{\mu_p\rho_N\tau_p\ln\frac{1}{1-\alpha_{NPN}}}\tag{2}$$

If α_{NPN} is relatively high, J_S is very well approximated by

$$J_S\sim\frac{W_N}{\mu_p\rho_N\tau_p\ln\beta_{NPN}}\tag{3}$$

where β_{NPN} is the grounded-emitter gain of the *n-p-n* portion of the structure. This expression contains most of the essential features of the more exact expression derived in reference 3 and is given here as useful for design purposes. Not apparent in equation 2 is the existence of a value of W_N for which $J_S=0$. Values of W_N less than this minimum result in switching without the mechanism here described. Equation 2 or 3 indicates that the turn-on current (current in the load) is directly proportional to the dimension W_N and is inversely proportional to μ_p, ρ_N, τ_p, and ln β_{NPN}. The inverse dependence upon the logarithm of β_{NPN} makes the turn-on current relatively insensitive to α_{NPN}. Fig. 2 shows experimental turn-on currents as a function of W_N in a set of devices in which area, ρ_N, τ_p, μ_p, and α_{NPN} were held constant; the turn-on currents exhibit the expected behavior as a function of W_N.

The condition that turn-on be field-dependent (and hence current-dependent) is given by

$$W_N>L_p\cosh^{-1}\frac{1}{1-\alpha_{NPN}}\tag{4}$$

Within the limits set by equation 4 considerable latitude in design is possible. The important design factor is the quantity

$$W_N/\left(\rho_N\left[\frac{q}{kT}\right]L_p^2\right)=W_N/(\rho_N\mu_p\tau_p)\tag{5}$$

W_N may be determined by practical considerations such as mechanical strength, etc. ρ_N may be determined by either the forward or reverse breakdown voltage (avalanche voltage) desired. The mobility μ_p is dependent upon the semiconductor material. Lifetime τ_p is controllable over several decades and thus is the major independent variable.

It should be mentioned that since the load current at which switching occurs is designable, this in some measure allows control over the current I_b which will produce switching. It has previously been shown[3] that the current I_b which leads to switching may be approximated by dividing the current as given by equation 2 by $\beta_{NPN}=\alpha_{NPN}\cdot(1-\alpha_{NPN})^{-1}$.

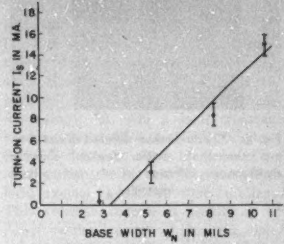

Fig. 2. Oxide-masked diffused-silicon n-p-n-p turn-on characteristics (diameter 105 mils)

If the *p*-type emitter forms a high breakdown voltage junction with the *n*-type base (W_N), it is immediately apparent that the device will exhibit a high PIV (peak inverse voltage). If an *m* (for metal) region is substituted for the *p*-type emitter, a switching structure is still possible (if $\alpha_{NPN}+\gamma_m>1$) but generally is of low PIV.

An All-Diffused P-N-P-N Structure

It is possible to produce an all-diffused structure of the type shown in Fig. 1. A process for producing high-alpha *n-p-n* structures in silicon has been previously described.[5] The diffusion is carried out in a sealed quartz tube with the concentration of two impurities (gallium and phosphorus) being controlled by the temperature and composition of an alloy source consisting of silicon, gallium, and phosphorus. This is immediately adaptable to fabrication of *n-p-n-p* switches by alloying a *p*-contact (say aluminum) to what normally would be the high-resistivity collector region. The inverse (blocking) characteristics of such a device

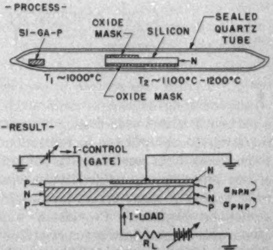

Fig. 3. Oxide-masked diffused-silicon n-p-n-p controlled rectifier

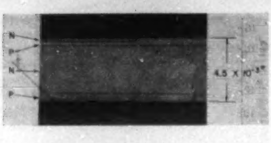

Fig. 4. Oxide-masked diffused-silicon n-p-n-p controlled rectifier (switch) showing simultaneous diffusion of n- and p-type impurities

would be determined by an alloy junction, and very good control of the alloying is required for reproducible characteristics. An alternative fabrication procedure is to oxidize one side of the silicon wafer prior to diffusion. The oxide layer effectively blocks the diffusion of phosphorus but has practically no effect on the diffusion of gallium.[6] On the oxidized side of the wafer no *n-p-n* structure is formed; rather, a *p-n* junction results. The over-all structure is thus *n-p-n-p* with the diffusion process determining the thickness of the internal *p*-region (one base) and the over-all wafer thickness determining essentially the thickness of the internal *n*-region (other base). The data in Fig. 2 were taken on structures formed in this manner on a single wafer of graduated thickness.

Contact to either of the interior regions (base regions) is required for 3-terminal operation. For the field alpha-varying mechanism to be effective, control of the current through the entire *n*-type base region is desired; this is most easily accomplished by varying the base current to the high-alpha *n-p-n* structure. Contact to the *p*-type base region can be made by alloying aluminum through the *n*-type emitter. A far superior method is to utilize again the properties of a thick oxide layer to obtain a more optimum geometry. If part of the upper surface, Fig. 3, of the silicon wafer is oxidized and subsequently the diffusion operation is performed, a surface *p*-region is produced under the oxide which is continuous with the base region of the *n-p-n* structure. A photomicrograph of a typical such structure is shown in Fig. 4. Nonpenetrating or slightly penetrating contacts may be affixed to the three separate surface regions by various well-known means. For example, gold and/or aluminum may be evaporated and alloyed to the appropriate regions, or alloys such as lead-silver may be used as desired.

Characteristics of the devices are similar to those previously described.[3] A composite illustrative characteristic is given in Fig. 5 where I_g represents control (or gate) current. In 2-terminal operation ($I_g=0$) forward breakover voltages of the order of 200–600 volts are obtained. Comparable peak inverse voltages are obtained. Turn-on currents of the order of 1 ma (milliampere) are usual for devices of 0.01-square-centimeter cross-sectional area. Control (gate) currents for turn-on are generally of the order of 0.01 to 0.1 ma for signal devices (less than 1-ampere load currents) and 0.1 to 10 ma for power devices. Forward voltage drops are very low; the voltage across W_N required to maintain α_{PNP} at the value required for switching is of the order of 0.1 volt. The total voltage drop across the device can be 0.6 volt or less in small devices. Values of 0.8 volt are observed for larger devices operating in the ampere region. Structures of 0.25-square-centimeter area have handled currents in the range of from 20 to 30 amperes.

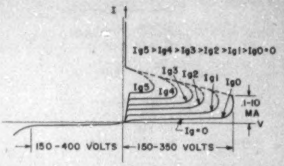

Fig. 5. Typical voltage–current and control characteristics of oxide-masked diffused-silicon n-p-n-p controlled rectifiers

Mechanization of Toll Switching at Providence, R. I.

C. W. ANDERSON
ASSOCIATE MEMBER AIEE

H. N. THORNTON
ASSOCIATE MEMBER AIEE

THIS PAPER was written to present an operating engineer's viewpoint of a particular nation-wide dialing installation from its conception to its realization. Providence, R. I., was chosen as subject of this presentation as this city appears to be typical of many others that are in service or proposed. Providence was chosen also because here is found utilization of a wide variety of the available instrumentalities and plans to incorporate probable future instrumentalities.

Previous papers have been concerned with the various requirements for nation-wide dialing as well as with major features available with various switching systems. This paper is, in a sense, a sequel to the previous papers, which were presented from a design engineer's viewpoint. This presentation is in the frame of reference of a using or application engineer.

The application engineer utilizes the selected products of the design engineer's labors to fill the peculiar combination of needs in a particular area. Forearmed with the knowledge of the requirements for nation-wide dialing, the numbering, switching, transmission, charging, signaling plans, etc., and the instrumentalities available to fulfill these requirements, he then considers the local needs.

Providence is like any other city in that its telephone needs reflect the local economy and geography and indirectly that of the neighboring area. Providence is the capitol of Rhode Island, and is located at the head of Narragansett Bay;

Paper 58-1246, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted January 9, 1958; made available for printing September 5, 1958.

C. W. Anderson and H. N. Thornton are with the New England Telephone and Telegraph Company, Providence, R. I.

see Fig. 1. It is the largest city in Rhode Island. The manufacture of jewelry and textiles and also of machine tools is important in this area. Summer tourist business is heavy along the coast line of Rhode Island and nearby Cape Cod in Massachusetts. Various military installations are significant in the area; Newport Naval Base is one and Quonset Naval Air Station another.

Telephone History of Area

The first factor to take into consideration is the telephone history of the area. The Providence toll office, to be here called Eddy Street, was installed in 1916 in leased space adjacent to a downtown local manual office. It was a no. 1 toll board and was all nondial as it has remained. This toll board was allowed to grow to meet the city's inward and through requirements and also the toll center's outward requirements. In the same leased building toll terminal facilities were installed and expanded throughout the voice-frequency era. In 1923 the conversion of local offices to dial began in the then new Washington Street building. Inward calls to this original panel office were switched under control of cordless *B* boards, assistance traffic was handled on a one-cord semimechanical board, and all outward toll calls via the Providence toll office. Nonticketed local calls were completed via panel call indicator (PCI) display at the terminating manual office.

As panel offices were added interpanel unit connections were provided by revertive pulse interoffice trunks. Handling of toll calls remained the same. Assistance calls were handled via the semimechanical board for the first two panel units and a dialing board with two cords was provided for the third unit. Two additional panel units were added in the Broad Street building under similar switching conditions except that the dial system "A" (DSA) board at that location was a type which provided key pulsing with two cords.

DSA boards had dial or key pulsing trunks to their own panel unit for local intraunit completion or through the local unit to a distant panel office with the local unit converting the call to revertive pulses. Local calls to manual office were completed also on direct trunks using PCI pulses.

At this point it is interesting to note that the two tandems now serving Providence had their beginning in about 1927. At that time Providence manual toll tandem was established as a means of providing switching access to manual toll lines from local manual and DSA boards. This manual toll tandem was a pioneer installation and was established for the purpose of completing station-to-station short-haul toll traffic and to relieve the Eddy Street outward toll board. This was the first of a series of checks on the growth of the Eddy Street toll office since outward position relief had been obtained elsewhere.

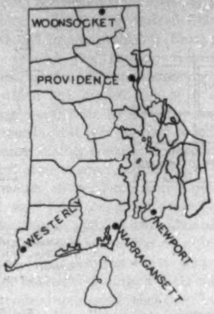

Fig. 1. Map of Rhode Island

About the same time a local manual tandem was established in the Washington Street building to serve local manual and DSA operators in reaching certain other city offices and selected nearby toll points. Inward terminal traffic from nearby toll centers was also switched through this board.

As growth and conversions continued, no. *1* crossbar was introduced into the area in Washington Street in 1940; however, as a wartime protective measure the unit was held in reserve and out of service until 1945. With the introduction of no. *1* crossbar the general method of switching remained the same except that as the unit expanded in 1948 a *3C* combined toll and DSA board was provided in Washington Street for this unit. This board handled assist traffic by d-c key pulsing, to or via its own crossbar unit to local city dial stations. Outward toll calls were switched from this board via the manual tandem toll board at the Eddy Street toll office. At that time expanded toll dialing was anticipated and the replacement of the Eddy Street toll office was probable in the not too distant future.

Shortly thereafter, no. *1* crossbar offices were provided in the Broad Street building and also in Pawtucket with similar switching arrangements and their own combined toll and DSA boards.

The five panel units were not provided with office frames. Consequently, as the interunit trunking increased either trunk expansion by means of office frames or a crossbar tandem was needed to increase the switching trunk access. Accordingly, in 1949 a local crossbar tandem was installed in the Washington Street building to meet the expanding local trunking needs and to replace the local manual tandem in that building. This crossbar tandem is essentially a 7-digit tandem capable of receiving dial-pulse, multifrequency, or revertive pulsing. Out-pulsing capabilities include revertive and dial pulsing and completion via automatic trunks and PCI. All trunks on this tandem are one-way.

Inward access to the tandem was provided from the panel and no. *1* crossbar units with revertive pulsing including office brush and group selections. The DSA operators and combined DSA and toll operators reached the tandem via multifrequency keysets (one board by dials).

A single-cord key-pulsing *B* position was provided in the Washington Street no. 3*C* switchboard lineup to provide access to the tandem from the Eddy Street toll office. Also, dial cord dialing was provided on suburban manual offices for dial-pulse access to the tandem. Completion from the tandem was via revertive pulses to the panel and no. *1* crossbar units, dial pulse to the two community dial offices (CDO). PCI pulsing was used to the metropolitan manual offices. Automatic completion was used to suburban manual offices beyond the nonticketed range.

In addition, further relief was provided to the Eddy Street toll office with the provision of a few inward multifrequency and dial-pulse terminal groups to the crossbar tandem from nearby toll centers. These nearby toll points retained ringdown groups to the Providence toll office for via and overflow terminal usage. Also provided for the use of the DSA and combined DSA and toll positions were outward dial-pulse and automatic groups to nearby toll centers for first-choice completion to that toll center central office.

Thus the development of dialing in and around Providence has been followed to the point of considerable complexity. The final step before approaching the major undertaking was the dial conversion of the suburban offices to the no. *5* crossbar. Eight suburban manual offices were so replaced between 1951 and 1956. Additional combined DSA and toll positions provided operator services with multifrequency toll switch completion

direct from the boards to the dial office. These offices, being suburban, relied heavily on the tandem for intracity switching.

Multifrequency pulsing was used from the no. *5* crossbar offices to the tandem and dial pulse or revertive from the tandem. Short-life investment in PCI senders was avoided either by temporary back haul via the tandem for conversion from multifrequency to PCI to the manual offices or by the interim provision of direct automatic trunks. Cordless *B* boards were avoided by the provision of the single-cord *B* position in one of the combined DSA and toll board lineups for completion of inward calls from the toll office.

In anticipation of the eventual replacement of the Eddy Street toll office, recent carrier growth had been provided in the Washington Street building and extended, voice-frequency-wise, to the toll office.

These were essentially the conditions found about 1952 when a cost study was inaugurated to investigate toll mechanization for Providence. The results of this study indicated the wisdom of replacing the toll office with a crossbar tandem equipped for centralized automatic message accounting (CAMA) operation.

Committee Organization

In order to execute such an undertaking it was felt that a formal organization of committees was needed to coordinate the various activities; see Fig. 2. In the beginning a General Coordinating Committee was organized. This committee's representation included members from all interested departments. Intercompany participation was included as most of the major cities east of the Mississippi River were involved. While this committee was large, its usefulness lay in co-ordinating the generalities of the undertaking and in following and assisting in the progress of the various working committees.

In order to pursue the switching problems, a Switching Engineering Committee was established. To co-ordinate the engineering of the toll line facilities, a Toll Plans and Procedures Committee was provided. A Programming Committee was established, and published a timetable of events for each of the various equipment orders needed by the Switching Engineering or the Toll Plans and Procedures Committees; see Fig. 2.

With this portion of the committee organization established, the project got underway. The first major consideration was whether a new tandem should be provided or the same switching accomplished by additional features and equipment on the present Providence crossbar tandem. The addition to the present tandem would cause a full tandem marker group to be reached within the decade and a new tandem would still have to be provided. Then intertandem trunking would be a problem. It was decided to provide a new toll tandem, equipped for 2-way trunking, inward and through toll service, outward operator, and CAMA switching, and also outward switching for 1- and 2-party subscribers for local automatic message accounting (LAMA) offices.

It was decided to exploit the present tandem by reducing it to an intracity tandem. It would handle base-rate coin, flat rate, and one-unit message-rate subscriber-dialed traffic, as well as intratoll center LAMA and operator-dialed traffic. The remaining capacity was used by inward terminal-grade high-usage trunks from nearby large toll centers including Boston, Mass., and New York, N. Y.

Significant decisions concerning the switching engineering are many. In the nation-wide toll switching plan, Providence had been rated as a class *III* office (primary center) homing on Boston sectional center which, in turn, homes on White Plains regional center. Homing on Providence would be all toll centers in Rhode Island, Cape Cod in Massachusetts, and toll centers in between; see Fig. 3. The noncoincident busy hours of the industrial inland areas with their day and winter busy hours offered increased efficiency in the use of toll facilities in contrast with the summer and night busy hours of the Cape, Bay, and coastal areas.

With the various offices pegged as to their position in the switching plan, the Toll Plans and Procedures Committee ascertained the intertoll trunk groups required for the undertaking.

Changes in Toll Circuit Setup

Because of the speed and efficiency of the dial machine many direct groups from the dependent toll centers to distant cities were reduced in size or eliminated. This called for a considerable change in the toll circuit setup in that facilities had to be cut off and switched at Providence.

As a portion of the toll line facilities were to be replaced at cutover and the remainder at a later data with new equipment in the Washington Street building, it was decided to extend all toll cables to the Washington Street building but to splice through only the pairs needed for cutover. Tie cables were provided for voice-frequency extension from Eddy Street carriers, etc., to the hybrids and single-frequency equipment at Washington Street. Replacement of program, teletypewriter, and the teletypewriter exchange switchboard were also included in the work.

Over-all transmission improvement was included with the introduction of via net loss (VNL) transmission treatment to the intertoll lines. Via net loss arrangements were not available for the older DSA boards. Consequently it was decided to confine their dial office assignments to dial units within the building and to operate the trunks between the DSA board and the tandem at VNL+2. For the combined DSA and toll positions, VNL connections were provided with the tandem and VNL+2 connections to their assigned offices.

Switching considerations continued. The intertoll trunks totaled 1,388. Of the 52 distant intertoll points 42 were dial, and either dial pulse or multifrequency pulsing was used in and out. For the ten manual toll centers, four were reached with automatic operation. No ringdown applique was available at first for the other six, consequently inward completion to them from the machine was planned via a Washington Street switchboard. In lieu of intertoll trunk appearance in the toll board, all dial intertoll trunks appeared on the new tandem only, which had been named the Rhode Island tandem to distinguish it from the earlier tandem called the Providence crossbar tandem.

Before the number of additional *3CL* positions could be determined, the amount of subscriber-dialed toll traffic had to be estimated. The state of Rhode Island is numbering plan area *401* and the major foreign area to these subscribers is the eastern Massachusetts area *617*. Conflicts in code assignments in these two areas had been avoided and indications were that this could be continued until after 10-digit equipment became available for panel and no. *1* crossbar offices. Plans were laid for PCI pulsing from the panel and no. *1* crossbar offices to the CAMA tandem for 7-digit calls to all available offices in these two numbering plan areas. Ten-digit dial-pulse CAMA arrangements were provided from the no. *5* crossbar offices for completion to the same offices in the *401* and *617* areas on a 7-digit basis, and on a 10-digit basis to the New York City area *212* and the Philadelphia, Pa., area *215*. Completion to nearby numbering plan areas was avoided for lack of 6-digit translation in the Rhode Island tandem as multiple entry into these areas was required. Distant numbering plan areas were also excluded for lack of adequate code treatment and 6-digit translation in the Boston sectional center which has not been converted from a no. *4* type of machine. The feeling existed that dialing should be established to those points that offered the greater volumes of dialable traffic. For the remaining points for which the availability of adequate arrangements was in question and the volumes light it was planned to establish customer dialing when arrangements permitted after cutover and in lieu of future growth in outward toll board positions. One no. *5* LAMA crossbar dependent toll center was in need of switchboard relief and it was decided to dial pulse into the Rhode Island tandem the 4- and 8-part direct distance dialing (DDD) calls and postpone switchboard relief there possibly until some local means of recording that type of traffic is available. Another dependent toll center, a step-by-step office, which was in need of switchboard relief necessitating a basement and 2-floor addition for switchboard position space, was brought into the Rhode Island tandem on a dial-pulse basis using a *112* directing code. This relief may be permanent or until a means of recording charges is provided in the step-by-step office; see Fig. 4.

Inclusion of tributaries of dependent toll centers was omitted until either charging equipment is provided at the dependent toll center or other arrangements are made. This was deemed advisable as the dialable traffic offered was not significant. One Providence remote tributary, a CDO, was omitted from the CAMA service as major toll connecting cable additions would be required and were not otherwise needed for some time. The official private branch exchange in Providence was provided CAMA service with the digit "6" as a directing code. A nonused office code "Jackson 5" plus the extension number is passed to the CAMA operator.

Completion from the tandem tributaries was provided by revertive pulsing to the panel offices and revertive or multifrequency to the no. *1* crossbar offices. Multifrequency was used to the no. *5* crossbar offices, except that provision was made for completion to certain remote offices over a group common to both tandems if required and for this dial pulse-revertive was provided. Of course dial pulse was used to the CDO's either over separate groups or groups common to both tandems. As a reserve feature two small groups of overflow trunks were provided from the Rhode Island tandem to the Providence crossbar tandem for protection in completion to the tributaries. One group equipped with 2-decibel pads provides completion through the Providence crossbar tandem to intrabuilding dial units and the other without pads for completion through the Providence crossbar tandem to offices located 2 decibels or more from the building.

With the increased efficiency offered by operator toll dialing the DSA and combined DSA and toll position could handle the needs of more stations than before. The initial DDD traffic reduced the switchboard load and still more stations could be handled by the same available positions. At the same time the 113 positions at Eddy Street were being abandoned, but with DDD and operator toll dialing they could be replaced by a lesser number of new toll positions. Combining these two conditions resulted in only 22 positions being required at Washington Street.

Fig. 5. Rhode Island tandem trunking schematic

Incidentally, switchboard senders (d-c key pulsing in revertive pulse-out) were provided for the toll boards to reach the panel offices. The DSA boards that did not have 2-cord dialing were used for DSA traffic only. The corresponding toll traffic and both the DSA and toll traffic of all out of building tributaries were handled on the no. *3C* and *3CL* boards.

With these provisions the cordless *B* boards and the *B* operation in the *3C* lineup were eliminated except for a small post cutover cleanup of miscellaneous traffic such as from the test desk to the panel offices.

The extra *3CL* positions provided for the ringdown operation mentioned previously had an interesting twist. The conversion schedule for these ringdown toll centers indicated that sufficient positions would be released by their conversion to dial to permit the replacement of the DSA semimechanical board. However, subsequent delays in the conversion program and upswings in toll traffic have made it necessary to continue the use of this switchboard for a few more months. In fact, during the engineering of the project ringdown appliques permitting direct access from the tandem to these ringdown trunks became available and were used to offset interim increases in position requirements; see Fig. 5.

In the original planning of the job the CAMA tapes were to be shipped to the existing automatic message accounting (AMA) center in Boston. However, interim increases in the load in the Boston accounting center indicated the advisability of providing an AMA center in Providence. It was decided to provide minimum equipment quantities in Providence with wiring duplicating that in Boston thereby permitting the processing of the Providence tapes in Boston should such an emergency arise.

All of this equipment required space and for this purpose 56,000 square feet of office space was provided in a new 4-story building on a company-owned lot behind the Washington Street building. This 56,000 feet provided for the needs of those displaced by the equipment which was added in the Washington Street building plus the AMA center and some personnel previously in leased space. All other equipment was added in the 8-story Washington Street building.

Additional Committee Work

With further reference to the organization setup (Fig. 2), it is seen that the two engineering committees "mold the features" of the Project and the Program Committee, setting the sequence for each segment of the work operation. Through release of complete notes on each committee's work it was possible for all to follow the project. These releases included coverage of the various engineering decisions, the list of all intertoll trunk circuits, and a project folder which outlined the schedule for each shipment order, building work, and outside cable.

During the period that the major orders were being placed at the factory, additional committees were organized to handle the cutover work and preparation for the cutover. For this purpose a Cutover Committee was organized. It is well if the chairman of this committee can devote his full time to this work and also that he attend the Program Committee meetings throughout. The Cutover Committee consists principally of the chairman of the various working committees plus others as required. As the cutover work was great in this case several cutover subcommittees were organized. The project is most sensitive to the Intertoll Trunk Subcommittee and the chairman of this committee, too, must spend most of his time on this project. From the Toll Plans and Procedures Committee the toll layout sketches provide the first look at what is ahead. The committee estimates the cutover devices that are required and confirms this estimate as the toll circuit orders are released. This Intertoll Trunk Committee must plan its various work and test operations for execution within the allotted time period. Too, this group must specify to the installer the desired sequence in which items of a staggered installation job are needed. If possible this committee may influence the arrangements of some of the detailed toll circuit layouts as they might facilitate the cutover procedures. This committee must also verify that test and manpower provisions can meet the work time objectives. This committee, like others, reported its progress up through the other committees.

The cutover phase of the Intertoll Committee's work involves preparation and co-ordination of the execution of the detailed intertoll trunk cutover. These plans, of course, must be co-ordinated through higher committees but essentially, under the direction of the Cutover Committee chairman, the Intertoll Committee must carry to service the intertoll trunk part of the job.

The Exchange Trunk Committee is much like the Intertoll Committee in function except that it is dealing with different types of plant. However, its job deals more than with mere loop facilities, for with VNL type of operation, 2-decibel pads, impedance compensators, and voice repeaters are found on many trunks.

The Project Committee, under the chairmanship of the maintenance engineer is concerned with the installation, its job progress and quality. Through its periodic reports, the weak points receive necessary attention.

The Test and Analysis Committee was used in Providence to see that training of personnel to maintain the switching machine was adequate. This committee followed the precut maintenance test to see that every possible disorder was corrected. During the cutover phase this committee was in constant contact with all of the offices involved and was always sensitive to trouble, particularly that of an interoffice nature.

Another committee which should be mentioned is the Committee for Employee and Public Information. This committee was organized while the order was in the factory and laid its plans during that period. A major newspaper announcement was made one year before the cutover and the program began. Throughout the entire program the employees were informed, before the public was, on the various phases of the job. They received their information through direct meetings, printed releases, and bulletin board announcements. The public was reached through newspapers, clubs, billboards, mail, radio, and television. Demonstration units as well as sound films were prepared for television and club use. Direct contacts were made with all heavy toll users. Measures of the effectiveness of the program were obtained through precutover customer sample survey to determine final precut soft-spot treatment. Office codes not used for precut local dialing were intercepted and instruction applied as required as a precut measure.

Extension of this program into the post cutover period is a valuable means of combatting postcutover soft spots. The teletypewriter exchange switchboard as it developed could be cut in advance, therefore, a separate committee was organized to handle the job. This was done primarily to relieve those concerned with the tandem project.

Another committee, the Performance Committee, was organized a few months before cutover. This committee gathered precutover customer performance data as a base for its operation.

For the cutover control itself a suite of offices was employed. Segments of one room were used for control of the exchange and intertoll trunks. Each had a group to follow specific phases of trunk release, test, and cutover. Elaborate paper-work procedures were established to provide clear indications of each work status and to slow down or stop any desired operation.

In one room the Performance Committee representative compiled all the data for speedy evaluation. Each operation was supervised by a person who could evaluate and analyze rather than be distracted with the actual performance operation himself.

Various members of the local and visiting staffs were posted as to the job's over-all progress in a briefing room. To this room were fed the various data for posting on bulletin boards. Other boards and booklets were available to explain the project's description.

The cutover was good. The difficulties encountered during the various phases were made easier by teamwork and co-operation, which is the way the telephone system works.

In the days and weeks following the cutover the Performance Committee met and reviewed and analyzed the data obtained from the equipment, traffic, and plant readings, operators' assistance tickets, service-observing information, and reports by the operators to the toll repair desk. From these analyses tests were indicated, troubles cleared, and customer instruction accentuated.

This task is not yet completed; improvements and additions are planned. New features, automatic number identification, 6-digit translation, 10-digit multifrequency CAMA senders are eagerly awaited. One addition is now on order and another being planned. Growth forecasts now show that in the early 1960's the marker group will be filled. Studies have begun to determine what is next.

Conclusions

In the earliest engineering phase possible the trunk list, particularly the list of intertoll trunks, should be released. The work of many must await these data. Probably the two engineering committees could be combined into one committee charged with starting the job, and the more thoroughly it performs its assigned function the smoother the road ahead will be both for itself and other groups that follow. Issuance and subsequent reissuance of charts and job description will aid greatly in the analysis and understanding of the project. The more detailed the trunking charts are the better, for this chart is "job insurance." The detailed narrative or the job description will serve to supplement the trunk charts. These data will help to avoid misunderstandings between different organizations as to equipment function, circuit type, etc. Interconnections between systems need thorough review as to functioning compatability and also to verify that both ends are provided with equipment in adequate quantity and type. Although many feel that this committee completes its work when the orders are placed on the factory, it should be pointed out that as the job progresses and changes and adjustments are made, there is need for the committee's co-ordination since changes are inevitable.

To relieve the various cutover committees, it might be advantageous to establish a cross-wiring committee to serve as timekeepers and pushers with regard to cross-wiring operations.

The characteristics of the toll facilities at Providence made the toll cutover and precutover work difficult. Through circuits at Eddy Street had to be cut off and extended to Washington Street at cutover (plus several other involved operations). Because of such possibilities, it is well that the toll layout sketches and the toll circuit orders be released well before the testboard-to-testboard test begins. This will allow for further analysis and planning of the test and cutover work. Too, this provides time to execute preliminary circuit order work which must precede this testing. If possible, equipment required to derive any new circuits should be scheduled for service well before the testboard-to-testboard period. These additional facilities will provide room for the preliminary circuit order work and also make possible the reduction of traffic releases necessary during the precutover period.

Above all, engineering personnel, and others involved, should be permitted to spend sufficient time on the project, rather than rush on to other work.

Binary Communication Feedback Systems

SHANNON'S CODING theorem for a noisy channel[1] indicates that information can be transmitted as reliably as desired in the presence of noise, provided the transmitted rate does not exceed the channel capacity. In unidirectional systems the reliability may be improved by increasing the code length or the redundancy of the message.

Actually, situations seldom occur in which the communication is purely unidirectional. Instead, there is usually a return channel by which the transmitter is informed that reception is taking place, or by which the receiver replies to the transmitter. The question therefore arises whether the return channel can be employed to improve the reliability of the forward transmission with less complex equipment than that required by long codes. Feedback can improve the capacity of the forward channel only when the channel parameters are fluctuating, in which case it can, for infinite code lengths, increase the capacity by just that amount which would result from the transmitter independently having knowledge of these fluctuations. As will be seen, however, it can be quite effective in improving the reliability of the accepted message for a finite code length. Under certain conditions feedback can achieve a zero error probability with finite code lengths.

Feedback systems can be classified according to the type of communication carried by the feedback channel:

1. *Decision feedback,* in which the feedback channel is used only to report the decision of the receiver as to the acceptability of the received message.
2. *Information feedback,* in which the feedback channel is employed to report information about the received message to the transmitter, the decision to accept, or reject and correct, subsequently being made at the transmitter.

In either type of system, once a decision is made that the message cannot be interpreted, the transmitter may repeat, in whole or in part, the ambiguous message, using the same code, or by agreement the system may shift to a higher redundancy code, or both may occur. A separate classification of feedback systems can thus be made by distinguishing between fixed-code systems and variable-code systems.

The advantage of a variable-code feedback system is that the redundancy of the code can be efficiently matched to the interference. This permits the setting of an upper limit on the probability of error, whereas for a unidirectional link the redundancy must be chosen so that the error probability will not be excessive at the poorest signal-to-noise ratio which is anticipated.

The choice of the reliability parameter to be used in analyzing each of these systems should depend on the nature of the final decision process. The relative values of per-unit equivocation and error probability, for example, are ultimately determined by what might be termed the "final" decoder, i.e., the person who acts on or interprets the received information. If the act or interpretation is such that all errors in transmission are treated identically, then the error probability is the better criterion. If, however, the incorrect message is used, in conjunction with the conditional probabilities and the structure of the code, as a basis for determining the transmitted message, per-unit equivocation may be better.

Some feedback systems exhibit the property of nonconservation of message length, but the problem of determining the reliability parameter in terms of the usefulness of the system remains unchanged. The concept of per-unit equivocation can, of course, be readily extended by utilizing the conditional probabilities of message perturbation as the message length becomes indefinitely large. To extend the probability of error requires the interpretation of the error probability per word in terms of the error probability per message.

Another useful parameter in comparing the various feedback and unidirectional systems is average normalized transmission time. This is defined as the ratio of the number of digits transmitted to

the number of digits ultimately accepted, and thus represents the price, in increased transmission time, which must be paid to realize the error-reducing capabilities of feedback.

Decision-Feedback Systems

GENERAL DECISION FEEDBACK[2]

In a decision-feedback system an attempt is made to transmit a member of the set of messages x_i by transmitting initially the corresponding member from the set of symbols x_{1i}. If the received message indicates with an acceptable error probability that a particular member of x_i originated the transmission, the received message is so interpreted and the transmitter is correspondingly informed. The transmitter then proceeds with the next message.

When, on the other hand, the received message is considered ambiguous, the transmitter, upon being so informed, replies with the corresponding symbol from the set x_{2i}. In a similar manner, if the information contained in the two received messages is sufficient, the process is terminated and the next message transmitted. If the information received is still insufficient to permit a decision, the corresponding symbol from the next set x_{3i} is sent, and the process is repeated.

In an attempt to send a single message x_i, therefore, the transmitter will transmit, as demanded by the receiver, the corresponding set of symbols (x_{1i}, x_{2i}, . . .). The process will be terminated only when the receiver indicates that total information received is sufficient to permit a decision to be made with a specified reliability. This type of system is thus seen to permit a more efficient use of redundancy than is possible with a unidirectional system, which has no knowledge of the ambiguity of the received message.

DECISION MECHANISMS

The decision to accept or reject a message is, in general, based on some scheme for distinguishing those points in sample space closely associated with specific message points from those points which are too ambiguous. Such a scheme, for example, may utilize one of the several systematic codes such as those suggested by Hamming[3] and Slepian.[4] The coding problem is then to choose for a given code length such message words, out of all possible words, that the chosen words are at least $(2k+1)$ units from each other. Received words not more than k_1 units distant from a message word are interpreted as that message word. Under these conditions, more than $(2k+1-k_1)$ errors per word must occur before one message is misinterpreted as another, and the system is capable of correcting up to k_1 errors. Although a number of systematic coding schemes have been evolved which are adaptable to this detection scheme,[5–13] the general problem remains unsolved.

An alternate decision scheme may be based on the use of null zones[14] at the detector. In its simplest form this technique establishes such a zone at the receiver that the reception of signals within the zone indicates that the a posteriori probabilities of the two transmitted states are too nearly equal to permit interpretation without excessive error. The receiver then requests repetition of this ambiguous information.

This type of reception may be extended to code words by noting that the interpretation of some of the received digits of the code words as nulls constitutes the recognition of additional points in the sample space of the received words at half-unit distances from the conventional binary code points. Such a half-unit point, if sufficiently close to a message word, may be interpreted as arising from that word. Otherwise, the received word is considered ambiguous, and the entire word is repeated. Such a system, because of the multilevel nature of its reception, is capable of being adjusted to improve the information rate of the system, even without feedback.[14]

Double-null reception, which bisects the null zone and thereby retains polarity information, permits points in the sample space of the received words between those of the single-null system. This scheme is thus capable of further improving the information rate over single-null reception. However, single-null reception has been shown, under certain conditions, to be capable of achieving about one half of the improvement in information rate theoretically attainable by increasing the number of receiver levels without limit. Double-null reception is capable of achieving only a small improvement over single-null. One advantage of the double-null scheme, however, is the comparative insensitivity to the adjustment of the null level.

THE FEEDBACK CHANNEL

Most of the analysis to date has assumed the feedback channel to be error-free. When this situation exists, the information rate and the error probability of the direct transmission channel remain unaltered if the feedback loop is opened. The important advantage of the feedback loop is that the entire message can eventually be received at the specified error probability.

The assumption that the errors in feedback can be neglected is quite reasonable under many conditions. In the first place, binary transmissions are usually composed of basic code groups, representing the symbols of some message alphabet. If only one bit of yes-no information need be transmitted over the feedback channel for each code group in the forward channel, the effective signal-to-noise ratio in the feedback channel can usually be maintained at a considerably larger value than in the forward channel. Since, for most types of noise which are of interest, error probability decreases quite rapidly with increasing signal-to-noise ratio, the error rate of the return channel can usually be kept quite small compared with that in the direct channel.

Furthermore, if the probability of acceptance is appreciably different from the probability of rejection, coding of the null locations will result in a considerable reduction of the required feedback capacity. The more precisely the probability of rejection is known, the more efficient this coding can be.

TYPES OF DECISION FEEDBACK

Many systems are designed to operate at moderate to large signal-to-noise ratios. The simplest arrangement then consists of adjusting the system for best operation at high signal-to-noise ratios, where the probability of requiring corrective information is small. The corrective information may thus be weakly encoded without excessive reduction in efficiency by employing simple repetition, and the information contained in the rejected message may correspondingly be discarded. Such an approach has been designated "discarding decision feedback."

When a large reduction in error probability is required, the number of repetitions is on the average very large, and the amount of information thrown away by a discarding system is excessive. It is better, in such circumstances, to use cumulative decision feedback. In this system the repetitions of a given message are integrated until the resultant crosses one of the null-zone boundaries, at which time the appropriate decision is registered and the transmsion of the next message requested. The analysis of this scheme, which requires techniques

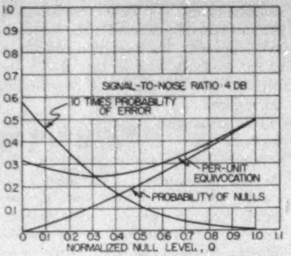

Fig. 1. Variations of parameters of binary symmetric decision-feedback (BSDF) system using single-null reception of uncoded binary pulses. Direct channel interference (DCI) is additive Gaussian noise. Feedback channel (FBC) is error-free

similar to those employed in the general random flight problem, has been worked out in some detail.[15] As expected, the method proves very powerful in reducing error probability.

When null reception is employed in a decision-feedback system, the receiver has the interesting option of terminating, or truncating, the feedback process at any time. Thus, for example, the receiver may elect, or may be forced by memory limitations, to terminate the feedback process after some specified maximum number of repetitions. In addition, the receiver also has the option of changing the null adjustment for each repetition of the same digit, either to optimize rate or to ensure a rapid convergence of the feedback process. It has been shown[16] that, for a large class of interference including additive Gaussian noise, the uniform-null nontruncated decision-feedback system is optimum, in the sense that a specified error probability can be achieved in minimum time. The effects of truncation will be discussed further in a later section.

PERFORMANCE OF NONTRUNCATED DECISION-FEEDBACK SYSTEMS

The behavior of decision feedback will be illustrated by examining the characteristics of several binary symmetric feedback systems. For simplicity the interference will be assumed to be additive Gaussian noise.

The behavior of an uncoded single-null-reception decision-feedback system is shown in Fig. 1. The parameter variations are presented as functions of the null level normalized to the noise-free received-signal amplitude. The initial improvements as the null level is increased from zero are due to the rejection of an increasing fraction of the digits which would otherwise be received in error. The important function of the feedback loop is not to increase rate, but rather to permit the entire message eventually to be received at the specified error probability. When the feedback channel is error-free, for instance, the information rate and the error probability of the direct channel remain unaltered if the feedback loop is opened. The degree of activity of the feedback channel is indicated by the probability-of-nulls relation. If the null level is raised past the optimum rate adjustment, the rate suffers as a consequence of the excessive fraction of rejections. In compensation, however, the error probability can be made arbitrarily small.

Fig. 2 shows the extent by which the rate of this system will vary when the feedback system is adjusted for operation at a given error probability. It should be noted that for a sufficiently large signal-to-noise ratio and a fixed error probability the reception reduces to that of a single-null system at the optimum rate. This optimum rate is, of course, better than that of unidirectional bilevel transmission.

For example, at a signal-to-noise ratio of 6 db (decibels) the unidirectional system has an information rate of 0.84 and an error probability of 0.06. The feedback system, adjusted for optimum rate, has an information rate which is about 4% better and an error probability which is 0.01. By introducing a sufficiently high null level the error probability can be reduced tenfold to 0.001 with a corresponding rate reduction of about 10%. To reduce the error probability a hundredfold to 0.0001 would require a rate reduction of 40%.

It can be shown that at large signal-to-noise ratios considerable improvement in the error probability can be obtained with only a small change in the null level. While the per-unit equivocation will correspondingly increase considerably, the information rate will remain approximately constant as long as the absolute value of the per-unit equivocation is low. This phenomenon is characteristic of most coding schemes, namely, that the schemes operate best when the signal-to-noise ratio is reasonably large.

The relation between error probability and transmission time for an uncoded uniform-null decision-feedback system is presented in Fig. 3. Theoretically the error probability can be made arbitrarily small at the cost of a sufficiently great increase in transmission time. Practically, of course, there are limits to the attainable signal-to-noise ratio and to the amount of time which can be allotted to transmission. These restrictions set a lower limit on the error probability.

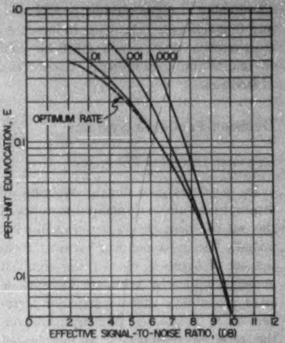

Fig. 2. Performance of uncoded BSDF system with single null adjusted for the specified error probability. DCI and FBC as in Fig. 1

A unidirectional repetition-integration system is shown in Fig. 3 for comparison, wherein each message pulse is repeated r times and integrated at the receiver before a decision is made. For convenience in analysis r is assumed to be continuous. It is seen that the feedback system is superior to the unidirectional integration system for short transmission times. For long transmission times, where the number of rejections

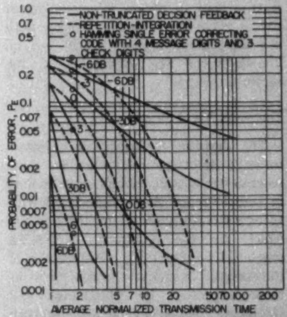

Fig. 3. Comparison of fixed-null nontruncated BSDF system with unidirectional system using Hamming error-correcting code. DCI and FBC as in Fig. 1

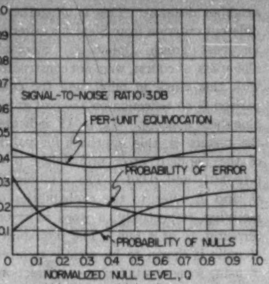

Fig. 4. Variations of parameters of BSDF system using double-null reception and 5-message-digit single-parity-check code. DCI and FBC as in Fig. 1

is large, the discarding process is very inefficient, and the integration system is better by far. If cumulative decision feedback is used, this drawback is overcome, since the feedback system then yields better performance at all values of transmission time, the asymptotic relation at large transmission times indicating a far lower probability of error than for either of the other systems.

Essentially this same comparison has been made for the case of reception in the scatter-multipath mode.[17] There the received signal is assumed to fluctuate with a Rayleigh distribution, and the null level is varied continuously in a manner which minimizes the error probability for a given transmission time. Comparison is made with a variable-integration scheme in which feedback is used to optimize the number of repetitions as a function of the received signal-to-noise ratio. Again the feedback scheme proves superior for short transmission times, and the integration scheme for longer times. Again, cumulative feedback is superior to both.

Comparison is also made in Fig. 3 with a unidirectional Hamming single-error-correcting code, operating with four message digits and three parity-check digits. The transmission time of this system is 7/4 that of the noise-free feedback system, for the same pulse rate. This system yields inferior results, as anticipated, because of its artificial constraints.

As indicated previously, binary transmissions are usually concerned, not with individual pulses, but rather with groups of pulses representing the symbols of some alphabet. The analysis must then be based on n-digit pulse groups, or words, where the per-unit equivocation and the error probabilities are calculated by noting whether the entire words, as entities, are properly interpreted and recorded.

Fig. 4 shows the behavior of a coded decision-feedback system using double-null reception and 5-message-digit single-parity-check transmission as the null level is varied. With double-null reception the interpretation of the received signal is identical to that of single-null reception except when multiple nulls are being received. Then, instead of always being rejected, the word is rejected only if parity does not check the digits indicated by the polarities of the nulls. With such a decoder the probability of error cannot be continuously reduced by increasing the null level, since very high null levels reduce the system to simple binary reception, as observed in Fig. 4. The initial effect of introducing the null level is to reduce the probability of nulls and the per-unit equivocation, and to increase the probability of error. This means that, while more words are accepted without being repeated, the probability of error of the accepted words is greater. This behavior demonstrates the previous remark that error probability and per-unit equivocation are not uniquely related to each other.

It is seen that, for a fixed signal-to-noise ratio, the ranges of variation of both the per-unit equivocation and the probability of error are limited. Also, the introduction of the null level initially increases the error probability, the value for large null levels returning asymptotically to the value for no null zone. These properties are in contrast with those of uncoded single-null reception where, by the introduction of the null, both parameters are initially improved, and where the error probability may be made arbitrarily small by increasing the null level, and hence the transmission time. A comparison may also be made with a coded single-parity-check single-null-reception system where, as the null level is increased from zero, the error probability initially increases, but ultimately becomes as small as desired, again at the cost of increased transmission time. Two obvious advantages of double-null reception over the single-null system are that the information rate for any setting of the null level is better than that of a system without nulls, and the null adjustment in the vicinity of the optimum rate setting is less critical.

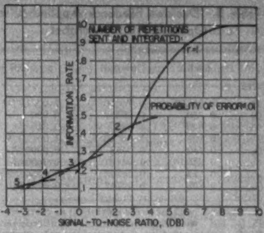

Fig. 5. Information rate versus signal-to-noise ratio for variable-code 5-message-digit single-parity-check BSDF. DCI and FBC as in Fig. 1

Fig. 5 is introduced to demonstrate the advantage of a variable code when the signal-to-noise ratio is not large. The curve is drawn for a 5-message-digit single-parity-check decision-feedback system. It is required to maintain the error probability at 0.01 or less. At low signal-to-noise ratios each digit is repeated several times by the transmitter and correspondingly integrated before decoding. For noise which is uncorrelated with the signal this results in an effective improvement in the signal-to-noise ratio, but causes a corresponding decrease in rate. The optimum arrangement, from the viewpoint

P_s, Q_s: Slepian's best alphabet without feedback.

of best rate commensurate with the reliability specification, is shown in Fig. 5. For example, below a signal-to-noise ratio of about 3 db, an error probability of 0.01 can be maintained at a higher information rate by employing single repetition. Below about 0.5 db, double repetition is better, and so on.

One of the main advantages of the feedback system over a unidirectional system is that this altering of the redundancy of the code can be done as the interference level changes. Hence the higher redundancy required at low signal-to-noise ratios need not reduce the information rate at high levels.

It is of interest to compare the performance of the single-null decision-feedback system with unidirectional systems using error-correcting codes. The schemes chosen for comparison are those tabulated by Silverman and Balser.[15] These are: 1. an uncoded m-digit-word transmission, 2. a single-error-correcting code using the minimum number of parity checks, and 3. an m-digit Wagner code. The feedback code chosen for comparison is the Hamming single-parity-check code of m information digits. The null level is considered to be adjusted for optimum rate. Table I reproduces this tabulation, adding the data for the feedback system. These systems are compared on the basis of the same noise-free rates.

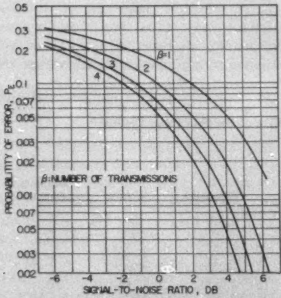

Fig. 6. Minimum possible error probability as function of maximum allowable number of transmissions per digit for uncoded BSDF system. DCI and FBC as in Fig. 1

It should be noted that, because of the rejection feature, the actual time required to transmit a message using the decision-feedback system is somewhat greater than that required by the unidirectional systems. This corresponds, over the range of m in this table, to an increase of from 23% to 40% for $\alpha=1$ and from 4% to 8% for $\alpha=1.5$. For greater signal-to-noise ratios the time devoted to repetition is negligible.

Another interesting demonstration is obtained by considering the application of Slepian's group alphabets concept to decision-feedback systems. Slepian's paper on group alphabets constitutes a significant contribution to communication theory, and his method of defining best group alphabets is elegant. One of his assumptions must be reconsidered, however, when the group alphabet concept is to be applied to feedback systems, namely, the assumption that a decision must be made on each n-group of pulses received, interpreting it as a letter of the alphabet.

In Slepian's scheme n-digit code words are sent, of which k digits carry message information. The 2^k letters of the alphabet form a group. The set of all possible received n-digit sequences are arranged in an array, with the letters of the alphabet forming the upper row. Any n-digit sequence, upon receipt, is interpreted as the letter at the top of the column of which it is a member. Each row except the top one constitutes a coset, and all elements of a coset require that the same number of digits be received in error. Slepian's best codes, essentially, are those which minimize the error probability for this type of decoding scheme.

This type of array can be utilized in a decision-feedback system. The receiver may interpret the receipt of any element of a coset as a null, or may distinguish between those cosets created by a sufficiently small number of errors and those representing several errors. In the latter instance the feedback system actually performs error correction with certain cosets, interpreting the elements of all others as nulls. It can be shown that the alphabets which minimize the error probability in this system are the so-called equal-distance codes of Hamming, i.e., those chosen to maximize the nearest-neighbor distance. This is altogether a different criterion from Slepian's criterion for best group alphabets. Slepian's alphabets, of course, were not constructed with this usage in mind, and the comparison is no reflection on the best group alphabets concept. Table II indicates the results of this approach for values of the per-digit error probability p of 0.1, 0.01, and 0.001. The symbols P, Q, and N refer to the probabilities of receiving, respectively, a word in error, correctly, or as a null. The probability of nulls is shown to be greatly reduced by using some cosets for error correction, albeit at the cost of an increase in the probability of error. The advantages of feedback are apparent in the drastic reduction in error which is achieved at the cost of a slight increase in transmission time.

PERFORMANCE OF TRUNCATED DECISION-FEEDBACK SYSTEMS

The optimum decision-feedback system employs uniform null adjustment for all repetitions, and prints a symbol only when the received signal falls outside of the null zone. With such a system there is, however, the possibility of encountering large delays before a digit is finally accepted. Such delays may exceed the memory capacity of the equipment, necessitating truncation of the sequence of repetitions. When the feedback process is truncated, it is no longer possible to obtain an arbitrarily low error probability, even at the cost of large transmission times. Fig. 6 shows the minimum attainable error probability as a function of the number

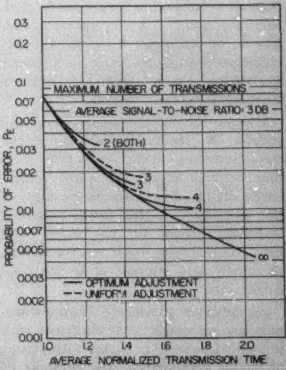

Fig. 7. Performance of uncoded truncated BSDF system. DCI and FBC as in Fig. 1

of forward transmissions β and the signal-to-noise ratio, when the interference in the direct channel is additive Gaussian.

It can be shown that in the region of large signal-to-noise ratio the introduction of truncation, with the maximum number of forward transmissions restricted to two, has the equivalent effect on the error probability of about a 2-db increase in power, as compared with the 3-db increase that results from sending each pulse twice, and integrating. The average time per message, on the other hand, is only slightly more than one half that of the integration system.

The optimally truncated system has the disadvantage that the null adjustment must be different for each repetition. Fig. 7 demonstrates that the increase in error probability which results from using a uniform null prior to truncation is small. The significant feature of truncation is the restriction on the possible reduction in error probability.

It can be demonstrated[18] that noise in the feedback channel acts substantially as truncation, i.e., it deteriorates the system and places a bound on the extent to which the transmission time can be exchanged for error probability.

Information Feedback Systems

GENERAL INFORMATION FEEDBACK[19]

The distinguishing characteristic of information-feedback systems is that all decisions as to what corrective information, if any, should be sent are made at the transmitter. The information carried by the feedback channel may be simple repetition of the received message, parity checks computed from the received message, or some more complicated code derived from the received message. By contrast, in a decision-feedback system, the feedback channel carries only yes-no information, which may be either coded or uncoded.

If the information fed back indicates that the message was probably received correctly, the transmitter proceeds with the transmission of the next part of the message. If an error is indicated, the transmitter sends a denial, or erasure, followed by corrective information. This may be done immediately, or at a later time, in coded form.

As a simple example, assume the set of message "words" is divided into several such groups that words close in message space are in different groups. The receiver indicates only the group to which the received word belongs. When the feedback process as well as the erasure information is error-free, this scheme assures that every finally accepted word is at least in the correct group. Since the coding may be so devised that the probability of receiving a wrong word from the same group is much less than that of receiving a wrong word in general, the error probability is greatly reduced.

With information feedback the transmitter has to provide additional capacity in order to keep the receiver informed, whether it is conveying new or corrective information, i.e., erasure capacity. On the other hand, the receiver gains additional information by knowing whether the original message is acceptable to the transmitter. It can be shown that, when the feedback is error-free, the gain in information at the receiver due to reduction in equivocation by the confirmation-denial or erasure, process is equal to the net information of the confirmation-denial signal.[19] Thus in these circumstances the proper use of an erasure signal does not cause a reduction in information rate.

The significant feature of information feedback, however, is not this conservation of rate, but rather the possibility of transmitting error-free messages without coding. This is possible if the feedback channel is error-free and of sufficient capacity to permit the receiver to inform the transmitter of the exact signal received via the direct channel. The transmitter can then, by means of the erasure process, correct all errors in transmission. The assumption of error-free feedback will be valid less often for information-feedback systems than for decision-feedback systems, because of the higher rates usually required of the feedback channel.

A general characteristic of feedback systems, not shared by unidirectional systems, is the possible nonconservation of message length. Whereas, for a unidirectional system the class of output messages is limited to those of the same length as the input message, for a feedback system output messages of all lengths are possible. Nonconservation of message length can occur only when the feedback channel is not error-free with regard to the distinction between the erasure word and the set of all message words.

For transmission of information which has intrinsic redundancy, such as English text, the nonconservation effect is not necessarily serious. The extraneous material and the missing material are probably detectable in the received message, if the effect is not too severe. For messages with no built-in redundancy, however, the nonconservation effect will cause dislocation of subsequent words, which may then in certain applications be considered totally in error. In such cases, the transmitted message should first be coded, to add redundancy, and information feedback used for further improvement of the reliability.

The amount of information contained in a received message is uniquely defined, irrespective of the problem of nonconservation, since there is a specific probability of the occurrence of each possible output message. However, for counting the number of errors in a received message, some artificial rule is necessary. If, for example, an error is counted each time one is made, the transmission of a single word may result in many errors. The corresponding error probability per word may therefore be greater than one. Again, in some systems where each undetected error creates a pair of message words or annihilates a pair, it may be desirable to count each such pair as one error. In some instances it may be desirable to base an error probability parameter on the exponent which describes the rate at which the probability of a message being entirely correct, as finally recorded, decreases with increasing transmitted message length.

It will become apparent that some types of information feedback have the effect of transferring part of the required system capacity from the direct channel to the feedback channel. This suggests that a compound system may be found which best utilizes the capacities available in any given communication system.

ITERATIVE DISCARDING INFORMATION FEEDBACK

An iterative discarding system is a simple information-feedback system wherein any message believed to have been received in error is corrected by erasing and then repeating. Since repetition does not make full use of the information contained in the discarded message, this simplicity of operation is obtained at the expense of rate. The feedback message need not be merely a repetition of that received from the direct channel. It may, for example, be just a parity check based on the received message.

In an iterative discarding information-feedback system, if the feedback message indicates that an erasure was incorrectly received as a message word, the transmitter sends two erasures, to erase both that message word and the preceding

TRANSMITTED: G O N θ N E θ θ θ E [] W I W I T H...
RETURNED: G O P θ N O T θ θ E [] W θ W I T H...

Fig. 8. Sequence of action in transmitted message. Erasure procedure indicated by arrows

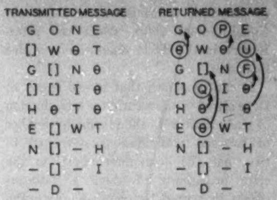

Fig. 9. Scanning of message. Circles indicate errors in reception

incorrect message. When the feedback message indicates that a message word has been incorrectly received as an erasure, the transmitter simply sends the preceding message and the intended message.

It is seen that one of the set of possible transmissions must be reserved for use as a erasure symbol. Confirmation, on the other hand, is implied merely by the transmission of subsequent information. The information that a particular message word is confirmed or denied is not entirely contained in the absence or presence of an erasure signal. To illustrate this point, an example of a discarding system with error-free and totally distinctive feedback will be given.

Consider that the message to be transmitted is GONE WITH THE WIND. Let [] denote a space. The sequence of action is shown in Fig. 8. The erasing procedure, indicated by the arrows, permits the correct message to be determined as GONE WITH. . .

From this example it may be seen that all succeeding letters serve further to confirm those already tentatively accepted. For instance, upon receiving the ninth message word, the receiver cannot be absolutely sure that an erasure was sent. If, however, some other message was wrongly received as an erasure, the transmitter would have sent an O as the tenth message instead of an E. Therefore, upon receiving the tenth message, the receiver becomes more certain that the ninth was correct. Of course, the tenth message could have been an O which was wrongly received as an E, but in that case, upon having an E fed back, the transmitter would next have sent θ instead of []. Thus, the error probability of any symbol, as evaluated at the receiver, goes to zero exponentially as the number of symbols received after the symbol in question increases. To make the error probability equal zero, one of two things is needed in addition to the error-free, totally distinctive feedback channel: an erasure word in the forward channel which cannot be transformed by errors into any other word, or an end-of-message signal that cannot be produced by errors from any other word.

One of the difficulties common to all types of feedback systems is the delay resulting from the spatial separation of the transmitter and receiver. A method of overcoming this difficulty, without stand-by operation, is to delay the correspondence between the corrective message and the original message. As an example, assume that the transmitter will receive the feedback message before transmitting the fourth succeeding letter. For convenience, arrange the message as follows:

G O N E
[ ] W I T
H [ ] T H
E [ ] W I
N D [ ]

The message will be sent by scanning each row in turn. Each column will then perform its own correcting; see Fig. 9, in which the circles indicate errors in reception. By applying the erasure rules, as indicated by the arrows, the message is recovered.

In this example the message was very short. If, for instance, the first chapter of the book *Gone With the Wind* were transmitted by this process, the number of errors in each column would be substantially equal. The time required to transmit the longest column would then be virtually equal to that required for the shortest.

In a nonfeedback system, in order to keep the coding length within reasonable limits, the rate of transmission usually must be adjusted to be appreciably less than the channel capacity. Information feedback accomplishes the same result as coding, namely, an improvement in reliability, and it also normally requires transmission at less than the channel capacity. The reasons for this loss in rate, however, are quite different from those of coding. In this case the three main causes of rate reduction are noisy feedback, rejection of the residual information contained in the erased word, and the loss of message entropy due to the existence of the erasure word.

The total signal entropy at the transmitter must equal the sum of the new message entropy and that required for the confirmation-denial process. Unfortunately, the entropy required for the confirmation-denial process is dependent on the system probabilities and hence on the signal-to-noise ratio. Thus an encoding of the system for one level of interference will result in less than optimum performance at other levels. The loss of entropy due to an unfavorable coding scheme is likely to be the most serious of the three losses when the erasure probability is high. Indeed, even with error-free feedback, this loss can result in a zero information rate even when the signal-to-noise ratio is only moderately low.

In general, however, noise in the feedback channel is the most undesirable factor in so far as rate loss is concerned. Such noise not only results in a direct loss itself but also causes the other two types of loss through an increased erasure probability. This points to the possibility of using partial information feedback to reduce the effectiveness of this noise. With less feedback information to transmit, the effective signal-to-noise ratio may be improved, with a consequent improvement in the feedback error probability.

A different situation exists when the noise in the forward channel is excessive. The direct channel transmission rate cannot be reduced without a detrimental effect on the information rate. It is possible to achieve some improvement, however, by introducing a null level and using both decision and information feedback. When in an information-feedback system the receiver is permitted the option of requesting a repeat, the feedback process then becomes compound feedback.

COMPOUND DISCARDING FEEDBACK SYSTEMS

One apparent advantage of compound feedback is that, by permitting the receiver to anticipate the transmitter, the number of erasures transmitted may be reduced. Since excessive erasure is usually the chief cause of loss in rate, compound feedback would appear to offer an improvement in this respect.

The mechanism of the compound feedback system is similar to that of an

Vol.
Pt. 1
195

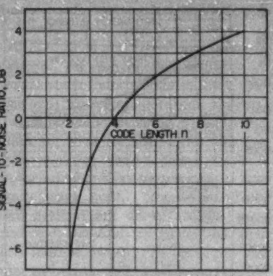

Fig. 10. Zero-information-rate signal-to-noise ratio of symmetrical-code-group repetition-feedback system. DCI and FBC as in Fig. 1

information-feedback system except that a "repeat" message is included in the set of feedback signals. The receiver sends this repeat signal back to the transmitter upon receiving an excessively ambiguous word. The establishment of a criterion of ambiguity is therefore essential to the operation of the system.

Every time a request for the repetition of a message word forestalls the use of an erasure, the transmission of an unnecessary erasure word in the direct channel is avoided. On the other hand, whenever repetition is requested of a word which would otherwise have been confirmed, an unnecessary word must be transmitted in the direct channel. An examination of the several factors which are involved indicates that, for a fairly noise-free system, the criterion of ambiguity is simply that the probability of confirmation be less than one half.

EXAMPLES OF ITERATIVE DISCARDING SYSTEMS

Simple Repetition Feedback

One of the simplest totally distinctive feedback systems is composed of symmetrical code groups, one of which is designated as the "erasure" symbol. When the feedback channel is error-free, this system permits the transfer of error-free information. The information rate is reduced over that of the corresponding unidirectional system by two effects: the use of a possible message symbol as an erasure, and the fact that no matter how an error occurs, two digits are nullified in correcting it.

At high signal-to-noise ratios the largest reduction in rate is caused by one code group being reserved as an erasure. At low signal-to-noise ratios, due to the annihilation of a pair of symbols for each error, there is a definite threshold below which the information rate becomes zero.

Fig. 10 shows the various threshold signal-to-noise ratios corresponding to a zero information rate for different code lengths and additive Gaussian noise in the direct channel. With a 5-digit code the rate becomes zero at one db. Codes having smaller lengths have lower thresholds, but then the information rate at high signal-to-noise ratios is lower because the seldom used erasure is a larger fraction of the available code groups.

One method of avoiding this threshold effect is to change the coding scheme as the signal-to-noise ratio varies. For example, a simple way of altering the transmission scheme is to employ consecutive repetition at the transmitter and integration at the receiver. The code may, in principle, be varied on a group-of-words basis or on an individual-word basis. Some direct channel capacity must be employed to keep the receiver informed about the code. The amount needed will be small if the code is not changed too often. This is the drawback which may prevent the transmitter from exercising control on a word basis.

Consider a system using 5-digit words. In the absence of repetition, the information rate is zero at a 1-db signal-to-noise ratio. By repeating each digit five times, error-free transmission becomes possible with a rate slightly less than one fifth that attainable at high signal-to-noise ratios without repetition. If the erasure procedure is not used, the information rate increases by about 5%, but the error probability becomes 0.02.

The effect of noise in the feedback channel may be partially determined by considering correct reception to occur only when the message is correctly received on a word basis. This definition neglects, however, the possibility that a sequence of events such as the

Direct channel transmission	0 Θ 0 1 1 1
Direct channel reception	0 1 1 0 Θ 1
Feedback channel transmission	
Feedback channel reception	1 Θ 0 1 1 1

may occur in an attempt to send 0111, so that even though errors are made on a word basis the final message is error-free. It is easily shown that, for small per-digit error probabilities in both channels, the error probability is proportional to the product of these per-digit error probabilities.

1	1	1	0	1	0	0	0
1	1	1	1	1	1	1	1

Complementary Feedback

Complementary feedback is identical to repetition feedback except that the feedback messages are not repetitions of the direct channel message. Instead, the complementary principle is employed: if two direct channel messages are close in signal space, their corresponding feedback messages are far removed, and vice versa. Specifically, if $d(x,y)$ is the distance between two direct messages x and y and $d(x',y')$ the distance between the two corresponding feedback messages x' and y', then such correspondence should be chosen that $d(x,y)$ plus $d(x',y')$ is approximately constant, or that the least sum is as great as possible.

Unfortunately, the problem of so choosing this correspondence is directly related to another unsolved problem, the problem of choosing, from 2^n symbols, such 2^m symbols that the least distance between the symbols is as great as possible. An approach to this problem may be made by examining the structure of the Hamming check-digit schemes.

One special case is that of $m=4$. In this particular case the system exhibits a neat symmetry wherein the sum of the distance between any two direct messages and the distance between the two corresponding feedback messages is always 4. In other words, for $m=4$ it is possible to pair off 2^m direct channel messages with 2^m feedback channel messages so that the sum of the distances is m, in all instances except $d(x,y)=4$, where the distance is $2m$. This arrangement is shown in Table III.

It should be noted that these feedback sequences can be indentified directly with the Hamming parity-check digits for a single-error-correcting double-error-detecting code. Such a code is, alternately, triple-error-detecting. For every m digits sent through the direct channel, c digits are fed back. Of these, (c-1)

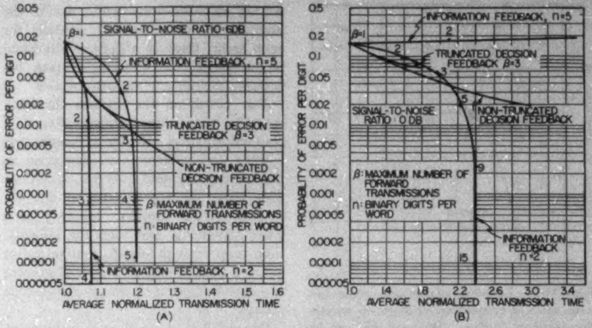

Fig. 11. Comparison of binary symmetric information-feedback and decision-feedback systems. FBC as in Fig. 1

A—When DCI is 6 db of additive Gaussian noise
B—When DCI is zero db of additive Gaussian noise

digits are used for single-error correction, the last one being a parity check over the entire set of digits in both channels.

It can be shown with complete generality that a symmetry between the direct channel and the feedback channel such as that shown here can exist only for word lengths of four or less. A difficulty arises for longer word lengths, in that the sequence of feedback digits is not always a unique indication of the received message. In fact, if there are four errors, which is the minimum distance in this code between sets of direct-channel plus feedback-channel sequences, the only cases not detected are those with the same check digits. To make identification totally distinctive, an additional identification digit must be sent over the feedback channel. Unfortunately, to make an undetected error in a word requires only four digit errors, but the number of such possibilities are reduced. Thus, although complementary feedback offers a slight improvement in some situations, it would appear that the problem of optimum coding for such an arrangement remains unsolved.

Partial Information Feedback

When the per-digit error probability in the feedback channel is not small, the probability of erasure may become excessive and greatly reduce the information rate. To minimize this effect the number of feedback digits per word may be reduced. This is then a case of partial information feedback.

There are various ways in which the feedback digits corresponding to a direct-channel word may be generated. One technique, for example, is to employ rules similar to the Hamming scheme over such feedback digits as are retained. It is difficult to state any general conclusions concerning this type of system. It accepts a reduction in the amount of information which can be fed back in exchange for an acceptable reliability of that which is fed back. As such, it offers definite improvement when the feedback channel is too noisy.

Compound Parity-Check Feedback

A partial-information system of the type just discussed may be converted into a compound feedback system by introducing a parity check into the direct channel or by employing null reception. The receiver can then, in addition to returning information concerning the received signal to the transmitter, exercise a limited power of decision regarding the acceptability of this signal. The object of this arrangement, of course, is to forestall a portion of the erasures which would otherwise have to be transmitted through the direct channel, and which have proved a major source of difficulty when the feedback is noisy. The price paid for the addition of decision feedback is that an additional "repeat" symbol must be available in the feedback channel or, alternately, one less information-feedback digit is available. Again, it is difficult to reach a firm conclusion in regard to the merits of this scheme, since no general optimizing procedure is known.

Noniterative Information Feedback

While the previous examples of iterative discarding systems can be very effective in error reduction, they suffer from one drawback, which, however, is avoidable. The requirement that every erroneous letter be erased immediately is wasteful of information rate, especially at high signal-to-noise ratios. This is due simply to the iterative mechanism, and is not inherent in information feedback, Consider, for example, an alternate system in which the transmitter sends either the entire message or some long, prearranged block of the message, meanwhile storing the information received over the return channel. At the end of this time, an erratum is transmitted which consists of coded error-position information, plus, in a coded system, corrective information. As this system minimizes the amount of information required to accomplish the erasures, the problem of a wasteful erasure mechanism is eliminated, albeit at the cost of increased storage requirements.

Truncated Information Feedback

In the nontruncated information-feedback systems previously discussed there is always the possibility of encountering large storage delays before a word is finally accepted. Since such delays may exceed the memory capacity of the equipment, there will, in a practical communication channel, be some maximum number of repetitions which cannot be exceeded. It is therefore of interest to evaluate the deterioration in system performance which results from truncation of the feedback process. The feedback channel is, for simplicity, assumed to be error-free, and the criterion of performance will be the average transmission time for a given error probability. This system is assumed to operate in the fashion of the simple, repetitive, iterative discarding system previously described.

As in noisy feedback problems, truncated information feedback results in the nonpreservation of message length. Thus the final message may contain erroneous pairs of words if an erasure is received as a word just prior to truncation, or a pair of message words may be deleted by the erroneous reception of a message word as an erasure. Because of this phenomenon it is difficult to determine word probability of error directly. It proves more convenient to calculate first the probability of receiving an entire message correctly and then to define an equivalent word probability of error as the message length is allowed to increase without limit.

In Fig. 11(A) and (B) a comparison is presented between the performance of two truncated information-feedback systems and two decision-feedback systems. The information-feedback systems are drawn for word lengths of two and five digits, and for various upper limits β on the number of transmissions of any one message word. The decision-feedback systems are drawn for the nontruncated case and for truncation after three transmissions. To facilitate the comparison, the per-word error probabilities of the information-feedback system have been recomputed in terms of equivalent per-digit error probabilities.

The information-feedback system shows a pronounced threshold effect in error probability with respect to the maximum allowable number of repetitions. The lower the signal-to-noise ratio or the larger the number of digits per word, the greater β must be before the error probability begins to decrease at a rapid rate. For values of β below this threshold the decision-feedback systems show a somewhat better performance. Above the threshold the error probability of the information-feedback system approaches zero at a rapid rate with little further increase in transmission time.

For the information-feedback systems illustrated the threshold effect occurs at about −6 db for two digits per word and at about one db for 5 digits per word. Fig. 11(B), which is drawn for zero db, demonstrates the effect of operating the 5-digits-per-word system below the threshold value.

The excellent performance of the information-feedback system above the threshold is primarily due to the control of the entire feedback process by the transmitter. It is noted that as the number of transmissions β is increased the storage requirements must be increased in order to perform the iterative discarding process. If a system having an isolated erasure digit is devised, this storage requirement can be maintained at that required for $\beta = 2$.

One method of avoiding the threshold effect, of course, is to change the coding scheme as the signal-to-noise ratio changes as, for example, by employing a suitable amount of repetition-integration with each digit.

A 6,000-Megacycle Radio System for Toll Telephone Service

M. H. KEBBY
ASSOCIATE MEMBER AIEE

A. F. CULBERTSON
MEMBER AIEE

THE RECENTLY developed Lenkurt type *74A* microwave system is designed for a capacity of 240 telephone channels per radio circuit over short-haul routes. Economic considerations in systems planning were based upon achieving a cost per circuit-mile which would compare favorably with new toll cable installations. Fig. 1 shows two views of a basic terminal.

Equipment design includes many new techniques and components, such as miniaturization, long-life klystrons, and ferrite devices. The nominal transmitter power output is 0.5 watt and the receiver noise figure is 14 db. Operating stand-by equipment can be used to protect service against both equipment and propagation outages, and may be applied on identical or alternate frequencies to the working channels. An alternate-frequency stand-by channel may protect up to three working channels.

Power may be supplied from normal 60-cycle sources, or a transistor inverter will provide 60-cycle a-c power from telephone central office battery, where available. A highly stable transmitter automatic frequency control circuit, employing magnetic amplifiers, holds the output frequency to substantially smaller variations than are required by current FCC (Federal Communications Commission) regulations.

Applications Objectives

The type *74A* radio system was designed to be an economical transmission facility for high-density routes over relatively short distances. Basic design considerations have placed primary em-

Fig. 1. Two views of basic type 74A terminal

phasis on the utility of this system in telephone plant. It is also expected to find applications in private communications systems where performance standards similar to those of the common carrier industry are required.

In establishing a cost objective for this system, present-day costs per circuit mile of conventional carrier on cable facilities were taken as a basis of comparison. With the increasing use of microwave in both the Independent and Bell System plant, most transmission engineers investigate radio as a matter of course when laying out new toll routes or major expansions to existing routes. In those circumstances where freedom from right-of-way problems and freedom from closely spaced carrier repeater points are attractive, the *74A* system is expected to become a useful tool in providing a high grade of telephone service.

The 1,200-kc base band is designed to handle up to 240 channels of frequency division multiplexing such as the Lenkurt type *45BX* or similar single side-band suppressed carrier equipment. A lesser number of channels with transmitted carrier can be handled if adjustment is made for the increased carrier loading.

The system is capable of operating up to four 2-way r-f (radio-frequency) channels in parallel with transmitters and receivers on a single antenna (eight with separate transmit and receive antennas). Separation between channels is achieved by means of a ferrite circulator. A block diagram of the r-f channel multiplexing arrangements is shown in Fig. 2. Reflection phase shift across the band of signal frequencies through the two circulators has been found to be essentially negligible, even to the r-f channel traveling the longest path. The transmitter and receiver of each r-f channel are connected into a duplex arrangement by a common waveguide assembly. Separation is by means of tuned waveguide filters. A ferrite isolator between the transmitting klystron and the transmission line minimizes pulling effects. The length of waveguide which may be used between the equipment and the antenna is limited only by the loss tolerable in the transmission path.

Operating stand-by arrangements permit the use of stand-by systems on either the same or different frequency assignments. Future planning for systems with alternate-frequency stand-by contemplate up to three working channels being served by one protection channel.

Every effort has been made in the design to assure the highest order of equipment reliability. Special long-life components and tubes are used throughout. The circuit has been engineered with the revenue-producing properties of telephone traffic in mind. Wherever possible, major subassemblies are arranged on a plug-in basis. This permits ready replacement of a defective subassembly once the trouble is isolated. Maintenance test points are brought out to the front of each unit, including the i-f (intermediate-frequency) amplifier, where they are easily accessible for routine

testing. Some of the more significant test points available, in this fashion are shown in Fig. 3.

The system has been designed for maintenance with the use of conventional telephone test equipment to the fullest extent possible. Provision for operation from telephone central office battery is expected to keep outage time due to a-c power failures to a minimum.

Characteristics

Channel Noise Performance

The system is engineered to keep noise from all sources at or below a value of 31 dba (decibels adjusted) at the zero-db transmission level point under average conditions. Intermodulation noise from telephone traffic on all channels is expected to cause the total to rise above this figure for not more than 1% of the time during the busy hour. Receiver noise due to propagation conditions may be expected to increase the noise above nominal for small percentages of the time. Table I shows the amount of noise expected from various sources on a typical section of a well laid-out system.[1] The relationship between channel noise and r-f input to the receiver is shown in Fig. 4.

Operating Stand-by

For the degree of service continuity normally considered necessary in commercial toll telephone service, the use of some form of protection facility is usually good engineering practice. For the type *74A* system, this protection facility was designed to be a second operating system to safeguard against equipment failures. An important secondary benefit is the increased circuit reliability because of the second propagation path available. On

Fig. 6 (left). Block diagram of typical repeater some applications over very short distances with only nominal reliability requirements, operation without a protection facility may be found adequate.

Applications with the protection channel operating on the same frequency and on a different frequency from the working channel are illustrated in Fig. 5. In either case, base-band information from the two receivers is combined in a combining and transfer panel for an average improvement in signal-to-noise ratio of 3 db (decibels) over signals from one receiver alone. Operation with stand-by on the same frequency is shown using two antennas at each station to obtain the benefit of space diversity reception of the r-f signals.

A protection channel on an alternate frequency permits a simple form of equipment arrangement and minimizes investment in antennas, towers, transmission line hardware, etc. A diversity path operating on the same frequency is somewhat more expensive to obtain because of the extra antennas and associated equipment required. However, in areas where frequency allocations are difficult to obtain, it will be preferred because of its more economical usage of the r-f spectrum. It will also be attractive on routes which grow to maximum occupancy of the available r-f channels in the common carrier band. For routes with larger circuit cross sections, the arrangement with one protection channel for three working channels will be preferable. This requires only a nominal use of extra frequencies for a protection facility, and also reduces the equipment investment.

Special Services Considerations

Telephone channels applied to the system may be expected to carry a variety of special services, along with message traffic. Foremost among these are voice-frequency telegraph, telephoto, facsimile, telemetering and SAGE (semiautomatic ground environment) data transmission. Considerable interest is being aroused in various forms of business machine data communications, and as this traffic develops it will be carried by the *74A* system.

Impulse noise, which has a particularly detrimental effect on some forms of high-speed data transmission, is expected to be relatively insignificant in this system. The switching time between diversity receivers is low enough that errors on teletype transmission should seldom oc-

cur. This low switching time (less than one millisecond) automatically provides a reasonable guarantee against wrong numbers on direct-distance-dialed calls.

Errors on high-speed data transmission systems such as SAGE may occur during the switching interval. However, with reasonable precautions in path layout, switches due to propagation effects should occur only at the rate of a few per day on a long-time average basis. This will naturally vary widely over different paths and with local propagation conditions. On routes with a heavy concentration of such data channels, switches due to propagation can be practically eliminated by adjusting the control circuits for increased tolerance to channel noise. In any event, the number of errors in SAGE data introduced by switches due to propagation should be quite small compared to the maximum permissible error rate. Switches due to equipment failures will naturally be as few as good design and good maintenance can possibly make them.

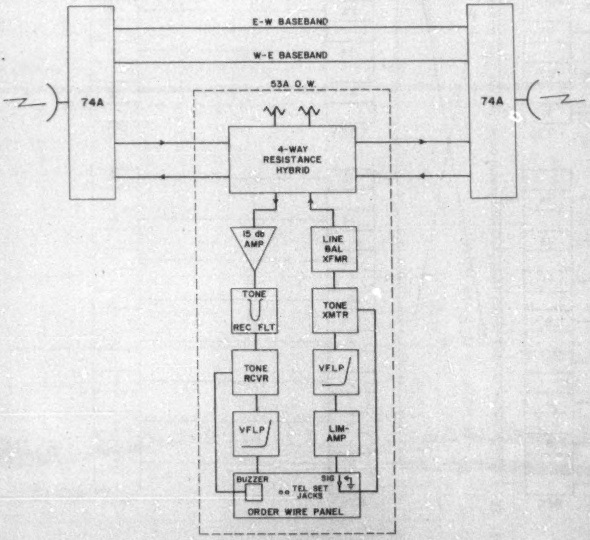

Fig. 9. Block diagram of typical order wire arrangement

REPEATER ARRANGEMENTS

A block diagram of a typical repeater point without diversity or stand-by is shown in Fig. 6. The repeater is composed of two back-to-back terminals. This makes dropout of carrier channels possible at intermediate points and simplifies service channel accessibility. The use of heterodyne or traveling-wave repeaters with this system is a possible future step in system development.

Frequency Allocations

Standard frequency allocations of the type *74A* system are shown in Fig. 7. These allocations are chosen to permit up to eight 2-way parallel r-f channels to operate over the same route, providing a maximum of 1,920 telephone channels in the common carrier band without stand-by. With one-for-three stand-by operation, 1,440 telephone channels will be obtained after deducting for the protection channels.

The allocations as chosen are intended to co-ordinate with those planned for the Western Electric type *TH* system. Two *74A* channels are assigned to the frequency spectrum occupied by one *TH* channel. It is expected that by following this co-ordination, frequency congestion at important terminal cities can be minimized.

ORDER WIRE AND ALARM FACILITIES

The lower 8-kc portion of the base band is brought to separate terminals for order

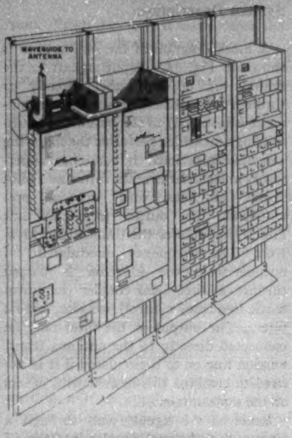

Fig. 10. Artist's sketch of typical 74A equipment in line-up with other toll terminal equipment

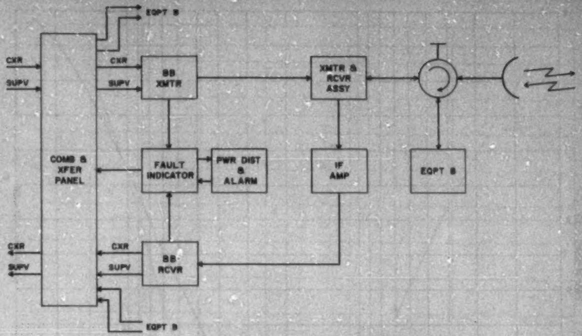

Fig. 11. Simplified block diagram of radio terminal

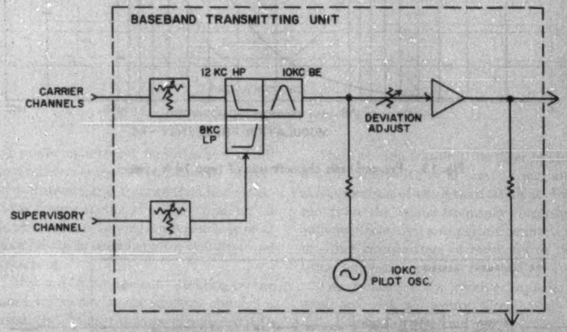

Fig. 12. Block diagram of base-band transmitting unit, which combines carrier and supervisory channels and inserts a 10-kc tone into transmission path

wire and alarm purposes. A new system, designated type *53A*, has been developed specifically for use with the *74A*. The type *53A* system is also capable of providing a universal order wire facility applicable to many other types of telephone installations.

The order wire shelf is shown in Fig. 8(A). The shelf is universally wired and is mechanically capable of mounting up to eight subassemblies of the type shown in Fig. 8(B). These mechanically identical subassemblies contain various necessary features of an order wire system such as voice-frequency amplifiers, pads, tone generators, tone receivers, etc. A total of 19 electrically different subassemblies are provided to build up the various order wire and alarm functions on a plug-in basis. A block diagram of a typical order wire arrangement at a through repeater point is shown in Fig. 9.

EQUIPMENT CONSIDERATIONS

The equipment is mounted on a standard 19-inch relay rack, with a 5-inch front projection. The total depth of the equipment is 10 inches. A complete terminal with power supplies and operating standby mounts in a vertical rack space of 9 feet, 3 inches. A terminal without standby occupies somewhat less than one half this space, since the combining and transfer panel and the waveguide circulator are not required. Access for maintenance is needed only from the front of the rack, permitting wall or back-to-back mounting of the equipment. Fig. 10 illustrates an installation of type *74A* equipment in a line-up with other typical telephone toll terminal equipment.

Waveguide arrangements are engineered so that they will be compatible with cable racks and relay rack line-ups in a typical toll central office. Outside plant associated with the type *74A* system can be arranged either with waveguide runs directly to the antennas or with antennas illuminating passive reflectors.

SAFETY PRECAUTIONS

The high voltages necessary for klystron operation have dictated special precautions to maintain the safety standards now prevalent in the telephone industry. Maximum voltage in this equipment is about 1,200 volts.

Positive-action interlocks are used under all power supply covers where voltages higher than 130 volts are developed. In addition to interruption of the primary supply, a special grounding relay is provided for immediate discharge of the high-capacity electrolytic filter condensers. Warning lights and labels are used to draw attention to parts of the circuit carrying dangerous potentials.

Protection against contact with the high voltage present on the repeller caps of the two klystron tubes is assured by the interlocked front cover of the r-f assembly. The necessary maintenance test points are accessible through the cover in such a manner that all routine tests may be conducted without interrupting service. A removable plate in the cover permits in-service tests of transmitter frequency in conformance with FCC requirements. Contact with high voltage through this opening is virtually impossible.

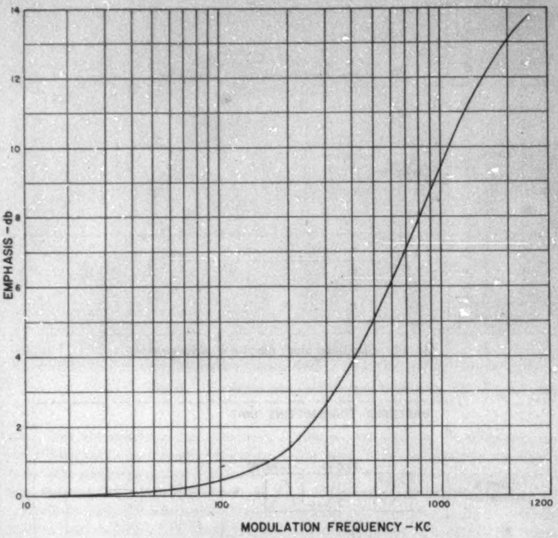

Fig. 13. Pre-emphasis characteristic of type 74A system

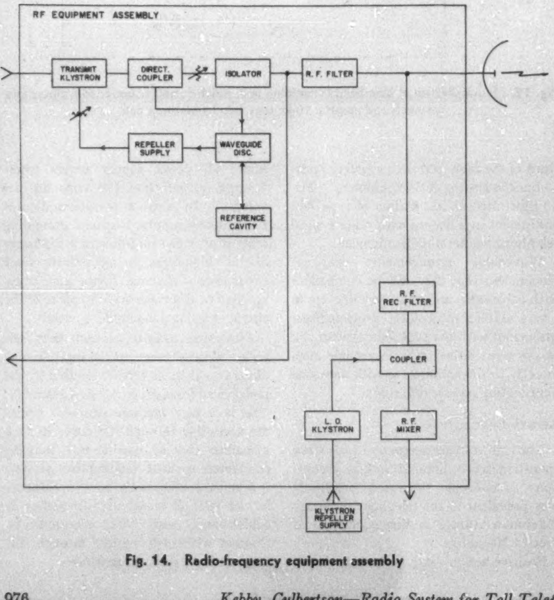

Fig. 14. Radio-frequency equipment assembly

System Description

A block diagram of the *74A* system is shown in Fig. 11. Input signals to the system are applied either directly or through a combiner (if stand by equipment is installed) to the base-band transmitting unit which performs the following principal functions: it combines supervisory and carrier circuits, furnishes a pilot signal, amplifies, and provides pre-emphasis. The output from this unit directly modulates the transmitting klystron. The frequency modulated r-f output from the klystron is passed through a directional coupler (for automatic frequency control), isolator, and r-f filter. The output of the filter may be connected directly to the antenna transmission line or to a circulator if it is desired to combine this system with others on the same antenna.

Received r-f signals pass through a filter and directional coupler into the r-f mixer. At this point the signals are mixed with a local oscillator klystron and the difference frequency of 70 mc (megacycles) applied to the i-f amplifier. An error signal from the output of the i-f discriminator is fed back to the local oscillator klystron to provide receiving automatic frequency control. The output of the i-f amplifier is amplified in the base-band receive unit which also provides de-emphasis and filtering of the carrier and supervisory circuits.

BASE-BAND TRANSMITTING UNIT

Two input connections to the base-band transmitting unit are provided: one for the telephone carrier channels and one for a supervisory channel. The carrier channel input accepts frequencies from 12 to 1,200 kc at levels from −10 to −40 db, and the supervisory channel accepts frequencies from 0.3 to 8 kc at levels from zero to −28 db. The impedance is 75 ohms for the carrier input and 600 ohms for the supervisory input. The carrier and supervisory circuits are joined through filters to provide an output base band that is continuous from 0.3 to 1,200 kc except for a 4-kc slot between 8 and 12 kc. This unoccupied portion of the base band is used to transmit a 10-kc pilot alarm tone generated in a transistorized oscillator located in this unit; see Fig. 12.

In a pure frequency-modulation system the noise in the base-band spectrum at the output of the receiver will increase at the rate of 6 db per octave unless some form of amplitude-frequency shaping (emphasis) is used. Fig. 13 shows the pre-emphasis characteristics of this system. From the curve it may be seen that the frequency deviation produced by a test tone in the top channel is about four times that of a test tone in the bottom channel. The frequency deviation is nearly constant throughout the lower portion of the base band from 12 to approximately 100 kc in order to minimize the noise generated by the klystrons. Shaping or pre-emphasis is accomplished through a resistance-capacitance network placed in the feedback path of the base-band amplifier. A bridging connection to the transmitting amplifier output is provided for sampling the 10-kc pilot to initiate alarm and transfer circuits in the event of component failure.

R-F EQUIPMENT ASSEMBLY

The output from the base-band transmitting unit is applied directly to the repeller of the transmitting reflex klystron in the r-f equipment assembly to produce a frequency-modulated output signal in the 6,000-mc band. With 240-channel busy hour loading plus signaling tones the resulting peak frequency deviation is approximately ±2 mc. The klystron has a nominal power output rating of one watt and is of the "heat sink" type; hence the need for fans and ovens is eliminated. Precise frequency control of the transmitting klystron is accomplished automatically by coupling a small portion of the output signal into a modified Pound discriminator. Comparison of the discriminator output with the reference cavity produces an error voltage which is applied to the klystron repeller to vary the frequency towards zero error. In this manner frequency stability considerably better than the present FCC requirement of 0.05% is obtained.

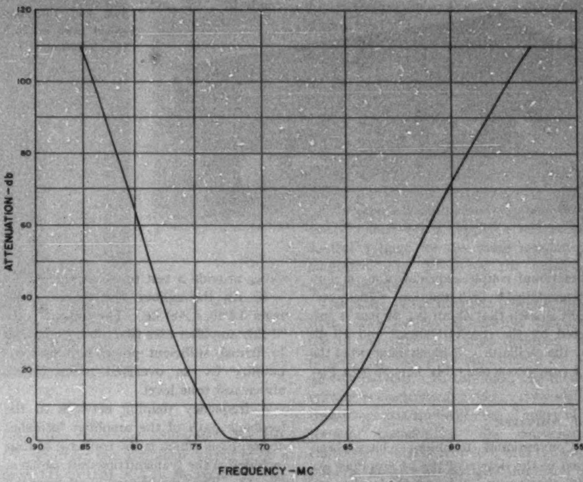

Fig. 15. Intermediate-frequency response characteristic

To provide an indication of the fade margin available in the system a variable r-f pad having a range of 30 db is provided. This variable pad may also be used to test r-f power monitoring facilities and to adjust receiver transfer equipment. To prevent antenna and transmission line reflections from causing klystron "pulling," a ferrite isolator having a reverse loss of at least 40 db is used between the filter and klystron.

If stand-by equipment operating on the same frequency as the working channel is used, the straight isolator is replaced with a switching isolator. In such cases, the stand-by transmitter is fully operative but is prevented from radiating by the 70-db reverse loss inserted by the switching isolator. This device is capable of switching in approximately one millisecond and is under the control of sensing circuits which detect loss of modulation or r-f power in the transmitter.

The 2-section transmitting filter having a 3-db bandwidth of at least 17 mc, and skirt rejection of more than 30 db at ±60 mc from the center frequency, furnishes sufficient selectivity to permit connection of other transmitters or receivers to the same antenna.

The input to the receive branch is equipped with a 4-section filter having a 3-db bandwidth of 17 mc and inserting at least 60 db loss at ±70 mc from the center frequency. This attenuation characteristic provides sufficient preselection to prevent adjacent channel interference or local oscillator radiation. In addition, it allows connection of other transmitters and receivers to a common antenna.

The local oscillator power is injected into the r-f crystal mixer through a

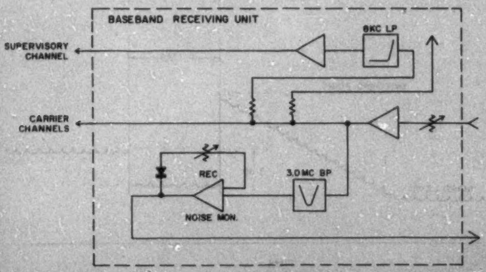

Fig. 16. Block diagram of base-band receiving unit, which separates carrier and supervisory channels and monitors out-of-band noise

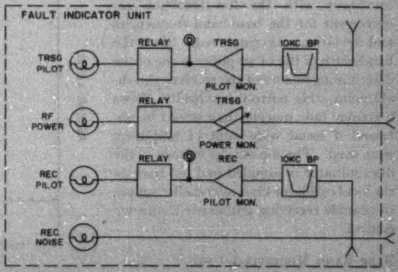

Fig. 17. Block diagram of fault indicator unit

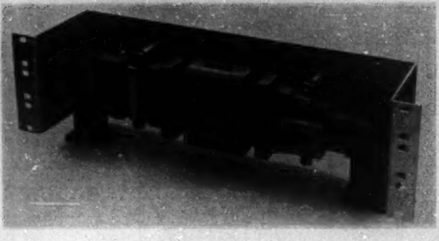

Fig. 18. Circulator panel used in 74A system

directional coupler equivalent to a nonsymmetrical hybrid junction. The power split is such that about 0.1 db loss is suffered by the received signal and 13 db by the oscillator. A block diagram of the r-f equipment assembly is shown in Fig. 14.

I-F AMPLIFER

Conventional techniques have been used in the design of the i-f amplifier except that types *408A* and *407A* tubes are used. The input stage uses the low-noise cascode design. The intermediate frequency is 70 mc and the amplifier furnishes a maximum gain of 90 db with a dynamic automatic gain control range of 60 db. This allows limiter saturation at the receiver threshold point yet insures that the amplifier will not be overloaded by a signal of up to 60 db above threshold. To insure that the gain will be maintained through tube aging, an additional 24-db gain margin is provided.

The discriminator has been designed to provide exceptional linearity over a wide band of frequencies to achieve the low degree of intermodulation necessary in a multichannel system of this type.

Typical i-f response characteristics are shown in Fig. 15. It should be noted that the bandwidth to the 3-db points is only 8 mc. This bandwidth has been selected to provide optimum performance consistent with the low-distortion requirement for the base-band frequencies and deviation ratio employed. Since the bandwidth of the i-f amplifier is one of the determining factors of the receiver threshold point, this narrow bandwidth allows a greater fade margin than would be obtained if usual wide-band i-f amplifiers were used. The d-c output voltage of the discriminator is sampled and fed back to the local oscillator klystron repeller supply to provide receiving automatic frequency control.

BASE-BAND RECEIVING UNIT

In the base-band receiving unit, three stages of amplification using type *408A* tubes provide a test tone output level of −15 db throughout the carrier band from 12 to 1,200 kc. The output stage of this amplifier uses two tubes in parallel to furnish sufficient power handling capability for an overload point 27 db above test tone level.

A frequency shaping network in the feedback path of the amplifier furnishes de-emphasis which is the converse of that included in the transmitting unit shown in Fig. 13. The supervisory band from 0.3 to 8 kc is filtered and amplified in a single transistorized stage to an output level of −4 db.

The 10-kc pilot generated in the transmitting unit is bridged off and fed to the fault indicator unit. In addition, noise at about 3 mc is filtered, rectified, and fed to the transfer and fault indicator units. Thus, both receiver noise and base-band pilot are monitored to furnish a complete indication of circuit condition. The base-band receiving unit is shown in Fig. 16.

FAULT INDICATOR UNIT

As shown in Fig. 17, the fault indicator unit contains alarm circuits to indicate failure of any active circuit in the system. The following points are monitored: the 10-kc pilot at the output of the transmitting and receiving base-band amplifiers, the transmitting klystron power output, and the receiver noise. An alarm condition lights a lamp on the face of the unit, actuates remote alarms if desired and initiates transfer to a stand-by system if equipped.

CIRCULATOR PANEL

The waveguide ferrite circulator panel has been designed to facilitate connection of more than one transmitter-receiver unit to a common antenna. It has an insertion loss of less than 0.5 db between ports and a reverse loss of more than 20 db. A single panel provides for the connection of up to three transmitter-receiver systems on one antenna; if desired, circulators may be cascaded to connect even more units to the same antenna provided the additional insertion loss is acceptable. The circulator panel is shown in Fig. 18.

COMBINING AND TRANSFER PANEL

When the system design provides for the use of stand-by equipment, both transmitters are modulated simultaneously with the carrier and supervisory information. Hybrid transformers located in the combining and transfer panel are furnished to provide this function. For this method of operation the receiver outputs are combined in a manner to allow the information content of the two receivers to add in phase or on a voltage basis; however, the noise adds on a random or power basis. Thus the signal-to-noise ratio through the combiner is

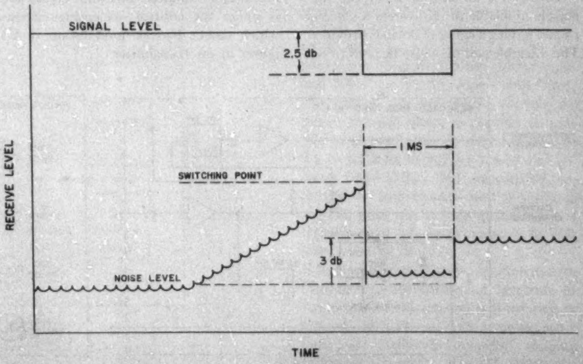

Fig. 19. Noise levels before, during, and after switching from one transmitter-receiver to another

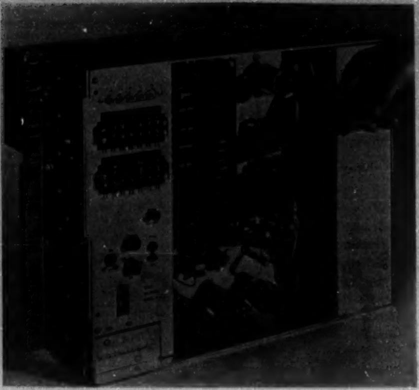

Fig. 20. Klystron power supply

improved up to 3 db over that of a single receiver when the signal strength to the two receivers is the same. Further, a decrease in intermodulation distortion products by an average of 3 db also results, since the distortion created in the two different systems is generally random in nature and not in phase.

When one of the receivers fades or fails, such as to allow the circuit noise to rise above some predetermined value, relays are actuated to disconnect and mute the noisy receiver. A control on the front of the combining and transfer panel permits adjustment of the switching point from a channel noise of 37 dba upwards. Thus, if high-speed data are transmitted over the system, it may be desirable to adjust the transfer point at 45 to 50 dba to minimize the number of switches that might occur during abnormal propagation conditions.

In the case of noise due to fading or upon forced maintenance switching, it takes less than one millisecond for the transfer from the combined output of two receivers to that of a single receiver. In the event of complete failure of one of the systems, approximately 35 milliseconds is required to silence any noise which may be present in the faulty equipment and to restore the signal level to normal.

During the switching interval, the signal level is reduced 2.5 db. After switching, the level is restored. However the signal-to-noise ratio is reduced by 3 db. This action is illustrated in Fig. 19.

POWER SUPPLIES

The system has been designed to take full advantage of the reliable source of power generally available in a central office. All the circuits using active elements, except the klystrons, have been designed for operation from 24 or 48 and 130 volts d-c.

Power for the klystrons is furnished from a supply which provides 6.3 volts d-c for the heaters and up to −1,200 volts d-c magnetically regulated for the various repeller and beam elements. In addition, magnetically controlled circuits furnish automatic frequency control for the transmitting klystron. The unit is designed for operation from 115 volts a-c, 50 to 60 cycles per second, either sinusoidal or square wave, with special care taken to minimize the effect of sharp transient variations in the supply main. All rectifiers are silicon diodes; three type *OD3* vacuum tubes supply a referenced control voltage for the main regulating amplifier. Fig. 20 shows the klystron power supply.

Operation of the klystron power supply from office battery is possible through use of an inverter panel designed to furnish 115 volts a-c from either a 24- or 48-volt battery. In this unit, the direct current is electronically chopped by eight transistors and applied to the primary of a toroidal transformer. The conversion efficiency is in excess of 90% and the output is a square wave with an amplitude of approximately 115 volts at a load of up to 200 volt-amperes.

At locations where 130 volts d-c is not available, a supply has been designed to operate from 115 volts a-c and furnish 130 volts d-c at up to 200 milliamperes with less than 10 parts per million of 120-cycle ripple. If only 24- or 48-volt d-c batteries are installed a second inverter of the type described in the foregoing may be used to supply the 130 volts d-c unit; thus, operation of the entire system is possible from only 24 or 48 volts d-c.

The Diode Reactance Modulator

G. FRANKLIN MONTGOMERY
NONMEMBER AIEE

Synopsis: The reactance modulator that uses one or two diodes to control the current in a capacitor is analyzed with the assumption of lossless circuit elements. Universal curves of susceptance, conductance, and control current, as functions of control voltage, are calculated for three basic circuits.

THE COMBINATION of two diodes and a capacitor to form a variable reactance was described as early as 1940;[1–3] more recently a single-diode circuit has been used commercially and by amateurs.[4] Such circuits are often used as frequency modulators, phase modulators, and automatic frequency controls. They are simple and convenient to apply, especially with semiconductor diodes, and apparently no detailed analysis of their operation has been published. It is the purpose of this paper to supply one.

Single-Diode Modulator

Consider the circuit of Fig. 1, where e is a sinusoidal voltage across which the capacitor C and diode D are connected in series, and E_B is a voltage that controls a direct current I. In practice, the source e is usually either the resonant circuit of an oscillator whose frequency is to be modulated, or the tuned circuit of an amplifier whose output is to be modulated in phase. E_B represents the instantaneous voltage of the modulating function; it is shown here as a battery without loss of generality, because the modulating function in any practical case varies slowly compared with the sinusoidal variation of e.

One is tempted at first to regard the diode simply as a resistor that is variable with I(or with E_B) and to proceed by referring to the known results of resistance tuning. Except for the trivial case where e is so small that the diode dynamic resistance can be considered constant throughout one cycle of e, it is obvious that the diode current is generally nonsinusoidal. The resistive assumption is therefore invalid.

It is more useful to regard the diode as a switch that is closed during some fraction of the input cycle and open during the remainder of the cycle, the period of conduction depending upon the current I and the other parameters. It may be expected that when the diode conducts throughout the cycle, the source is shunted by the capacitor C. When the diode remains nonconducting, the source is open-circuited, provided L is sufficiently large. For conduction during a fraction of the cycle, the impedance in shunt with the source should lie between these extremes.

Assume that the diode is ideal in the sense that it has zero forward resistance and zero reverse conductance. The circuit input voltage may then be defined as

$$e = E \sin \varphi = E \sin \omega t \qquad (1)$$

and an angle of diode conduction

$$\theta = \varphi_1 - \varphi_0 \geqslant 0 \qquad (2)$$

where φ_0 is the phase at which conduction begins, and φ_1 is the phase at which conduction ends. The inductor L is defined as one having infinite reactance at all angular frequencies equal to or greater than ω and zero resistance to direct current. With these assumptions, two statements may be made concerning Fig. 1:

A. During one period $2\pi/\omega$, no charge is accumulated by capacitor C.

B. During one period $2\pi/\omega$, the energy consumed by the load E_B equals the energy delivered by the generator e.

The equations equivalent to these statements are given in the Appendix. The solutions yield the ratios E_B/E and $I/\omega CE$ as functions of the angle of conduction θ, and plots of these functions are shown in Fig. 2. Note that as E_B/E decreases from unity to zero, θ increases from zero to 2π, and $I/\omega CE$ increases from zero to unity.

Of primary interest, however, is the fundamental component of current delivered by the generator. The total generator current i is sketched in Fig. 3, for $E_B/E = 0.171$, $\theta = \pi$. The fundamental component is, in general,

$$i_\omega = I_Q \cos \varphi + I_R \sin \varphi \qquad (10)$$

where I_Q and I_R are the amplitudes of the reactive and resistive components respectively. These are solved for in the Appendix. The fractional susceptance may then be defined as

$$B/\omega C = I_Q/\omega CE$$

and the fractional conductance

$$G/\omega C = I_R/\omega CE$$

These are plotted as functions of E_B/E in Fig. 4. The d-c term $I/\omega CE$ is plotted for convenience on the same graph.

The susceptance is evidently not a linear function of the control voltage E_B but has an approximately linear range for $0.15 < E_B/E < 0.25$. Determination of the exact point where $d^2B/dE_B^2 = 0$ is a problem that has not been solved, but it is convenient that this point occurs within a range where the Q of the admittance is reasonably large (about 3.7).

The circuit of Fig. 1 is directly useful in practice, but perhaps more general use has been made of the circuit of Fig. 5, in which the inductor of Fig. 1 is replaced by a resistor R large enough that its a-c conductance can be neglected. Note that E_C is shown with polarity opposite to that of E_B. The variation of susceptance with control voltage E_C is best solved for graphically, as illustrated in Fig. 6. A load line is drawn with slope $1/\omega CR$. The intersection of this line with $I/\omega CE$ represents the d-c operating

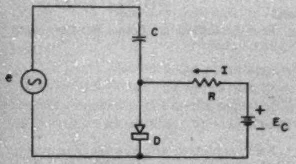

Fig. 5. Single-diode modulator with resistive control source

point for $E_C/E=0$, and the fractional susceptance is found by projecting this point vertically onto the curve for $B/\omega C$, at p_0'. For other currents, $E_C/E=q-p$, and the fractional susceptance is the vertical projection of p on $B/\omega C$, at p'. Note that the linear range of susceptance variation with E_C is now centered at $E_B/E\approx 0.25$.

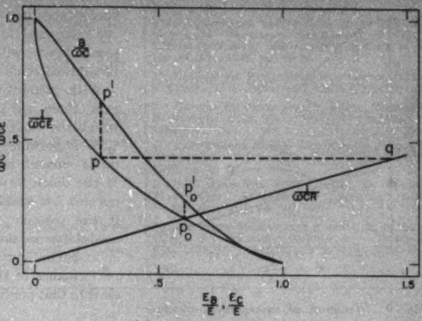

Fig. 6 (right). Graphic analysis of single-diode modulator with resistive control source

Dual-Diode Modulators

For the parallel-diode circuit of Fig. 7, definitions 1 and 2 again apply, with the qualifications that $\theta \leqslant \pi$ and that φ_0 and φ_1 are the limits of conduction for diode $D1$. Because of circuit symmetry, only the half-period $\varphi_0<\varphi<\varphi_0+\pi$ need be considered; during the remainder of the period, current i is a repetition of the first half-period current but opposite in sign. I_{DC} is defined as the direct component of current in the load E_B. In the Appendix, it is shown that $\varphi_1=\pi/2$, and with φ_1 determined, the only additional statement necessary for the analysis is the foregoing second statement B.

For the series-diode circuit of Fig. 8, definitions 1 and 2 apply, where φ_0 and φ_1 are the limits of conduction for $D1$. Again, because of circuit symmetry, we need consider only the half-period $\varphi_0<\varphi<\varphi_0+\pi$. Inductors L are identical with inductor L of Fig. 1. Now, however, it is evident that, to maintain current I, either $D1$ or $D2$ must be conducting, for every φ. It follows that $\theta=\pi$ and that, as a third statement

C. At $\varphi=\varphi_0$ and at $\varphi=\varphi_0+\pi$, there is no voltage drop across the diodes.

The analysis proceeds from this statement and from statement B.

The equations applicable to Figs. 7 and 8 are given in the Appendix, and the resulting functions are plotted in Figs. 9 and 10. For the parallel-diode modulator, the approximately linear range of fractional susceptance is centered at $E_B/E=1$, and it may be shown that $d^2B/dE_B^2=0$ at this point. Similarly, it may be shown that for the series-diode modulator, d^2B/dE_B^2 is nowhere equal to zero. An interesting and possibly useful result for the series-diode circuit is the fact that the fractional susceptance is proportional to the square of the control current over its entire range.

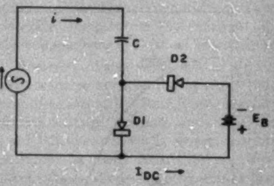

Fig. 7. Parallel-diode reactance modulator

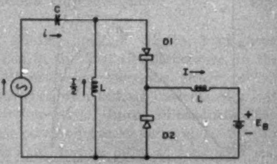

Fig. 8. Series-diode reactance modulator

Effect of Imperfect Diodes

The real performance of diode modulators may be expected to differ somewhat from that described by this analysis; real diodes have appreciable forward resistance, and most voltage sources across which the modulator is connected have appreciable impedance. Because of the difficulty of determining the effect of these impedances quantitatively, no attempt will be made to do so, but a qualitative explanation of the effect of diode forward resistance may be stated simply.

Suppose that the diode in Fig. 1 has zero reverse conductance and a positive forward resistance. For a given current

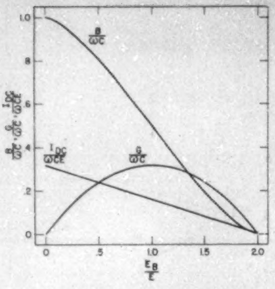

Fig. 9. Variation of susceptance, conductance, and d-c control current, with control voltage, parallel diodes

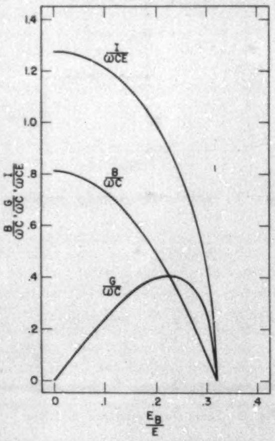

Fig. 10. Variation of susceptance, conductance, and control current, with control voltage, series diodes

i, the diode may be replaced by an ideal diode, as defined previously, in series with a zero-impedance generator of voltage $e_D(\varphi)$. Now,

$$e_D = E_D + e_{D\omega}(\varphi) + \ldots$$

where E_D is the direct component of e_D, $e_{D\omega}$ is the fundamental alternating component, etc. It is evident that E_D aids E_B; to obtain a given current I, therefore, E_B must be smaller than its theoretical value. Voltage $e_{D\omega}$ is in phase with i_ω and may be considered as an additional generator in series with generator e. Its effect is to modify i_ω so that it is more nearly in phase with e. The net result is that, for any I, the fractional susceptance will be less than its theoretical value, and for large I, the fractional conductance will be greater than its theoretical value.

With presently available diodes, however, there will be many applications in which the diode resistance is of no practical importance. Note that the peak diode current never exceeds $2I = 2\omega CE$. If the diode forward voltage drop for a current I is small compared with E, and if the reactive current drawn by the modulator is small compared with the short-circuit current of the source, real performance of the modulator should be close to that predicted by theory.

Experimental Applications

In addition to the previous references, successful use of these modulators has been made in two recent applications. The first[5] uses the circuit of Fig. 1 as an automatic frequency control to correct local oscillator drift in a frequency-modulation receiver. The second[6] uses the circuit of Fig. 7 to frequency modulate a 500-kilocycle oscillator in a wireless microphone. Of particular interest in this case is use of the d-c power $E_B I_{DC}$ to power transistors that amplify the modulating signal.

Appendix

Single-Diode Modulator

Consider the following definitions:

$$e = E \sin \varphi = E \sin \omega t \tag{1}$$

$$\theta = \varphi_1 - \varphi_0 \geqslant 0 \tag{2}$$

Then

$$i = C de/dt = \omega C de/d\varphi \tag{3}$$

for $\varphi_0 < \varphi \leqslant \varphi_1$

and

$$i = -I \tag{4}$$

for $\varphi_1 \leqslant \varphi < \varphi_0 + 2\pi$

From statement A

$$(1/2\pi)\int_{\varphi_0}^{\varphi_0+2\pi} i d\varphi = 0 \tag{5}$$

From statement B

$$\int_{\varphi=\varphi_0}^{\varphi_0+2\pi} ei\, dt = 2\pi E_B I/\omega \tag{6}$$

From equations 3 and 4

$$I/\omega CE = -\cos \varphi_1 \tag{7}$$

From equations 5 and 7

$$\tan \varphi_1 = -\frac{2\pi - \theta + \sin \theta}{1 - \cos \theta} \tag{8}$$

and from equations 6 and 7

$$E_B/E = -(1/4)(\cos \varphi_1) \times (1 - \cos \theta - \sin \theta \tan \varphi_1)^2 \tag{9}$$

which allows the plotting of Fig. 2.

The current of interest is

$$i_\omega = I_Q \cos \varphi + I_R \sin \varphi \tag{10}$$

whose coefficients can be calculated with the Fourier series equations, so that

$$G/\omega C = -(2E_B/E) \cos \varphi_1 \tag{11}$$

and

$$B/\omega C = (1/2\pi)[\theta - \sin \theta \cos \theta + 2 (\cos^2 \varphi_1) \times (2\pi - \theta + \sin \theta \cos \theta + \sin^2 \theta \tan \varphi_1)] \tag{12}$$

Fig. 4 is plotted using equations 7 through 9, 11, and 12.

Parallel-Diode Modulator

The term $\theta = \varphi_1 - \varphi_0 \geqslant 0$ is defined as the angle of conduction for diode $D1$. Then

$$i = C de/dt = \omega C de/d\varphi$$

for $\varphi_0 < \varphi \leqslant \varphi_1 \quad (13)$

and

$$i = 0 \tag{14}$$

for $\varphi_1 \leqslant \varphi < \varphi_0 + \pi$

From statement B

$$\int_{\varphi=\varphi_0}^{\varphi_0+2\pi} ei\, dt = -\int_{\varphi=\varphi_0+\pi}^{\varphi_0+2\pi} E_B i\, dt \tag{15}$$

From equations 13 and 14

$$\varphi_1 = \theta + \varphi_0 = \pi/2 \tag{16}$$

and from equations 15 and 16

$$E_B/E = 1 + \cos \theta \tag{17}$$

The direct-current term is

$$I_{DC}/\omega CE = -(1/2\pi CE)\int_{\varphi=\varphi_0+\pi}^{\varphi_0+2\pi} i\, dt = (1/2\pi)(1 - \cos \theta) \tag{18}$$

From calculation of the Fourier coefficients, as before

$$G/\omega C = (1/\pi) \sin^2 \theta \tag{19}$$

and

$$B/\omega C = (1/\pi)(\theta - \sin \theta \cos \theta) \tag{20}$$

Fig. 9 is plotted with the use of equations 17 through 20.

Series-Diode Modulator

The term $\theta = \varphi_1 - \varphi_0 \geqslant 0$ is defined as the angle of conduction for diode $D1$. From the definition of I, however, $\theta = \pi$. Then

$$i = I/2 \tag{21}$$

for $\varphi_0 < \varphi \leqslant \varphi_0 + \pi$

and

$$i = -I/2 \tag{22}$$

for $\varphi_0 + \pi < \varphi \leqslant \varphi_0 + 2\pi$

From statement C

Vol.
Pt. 1
1958

$$E \sin(\varphi_0+\pi) = E \sin \varphi_0 + \int_{\varphi=\varphi_0}^{\varphi_0+\pi} (I/2C)dt \qquad (23)$$

and

$$I/\omega CE = -(4/\pi) \sin \varphi_0 \qquad (24)$$

From statement B

$$\int_{\varphi=\varphi_0}^{\varphi_0+2\pi} ei\, dt = 2\pi E_B I/\omega \qquad (25)$$

and

$$E_B/E = (1/\pi) \cos \varphi_0 \qquad (26)$$

From calculation of the Fourier coefficients

$$G/\omega C = -(8/\pi^2) \sin \varphi_0 \cos \varphi_0 \qquad (27)$$

and

$$B/\omega C = (8/\pi^2) \sin^2 \varphi_0 \qquad (28)$$

Fig. 10 is plotted with the use of equations 24 and 26 through 28.

An Analog Frequency-Measuring Circuit Accurate to 0.1 Per Cent

J. MITCHELL
NONMEMBER AIEE

DURING the course of work on an electromechanical analog computer it was necessary to convert frequencies in the range of 2 to 20 kc into shaft rotations. The shaft rotation had to be proportional to frequency with a departure from linearity of less than ±0.1% of full scale. The circuit was required to operate over the temperature range of −55 to +55 C (degrees centrigrade).

A diode pump circuit,[1] which is a pair of diodes used as a switch alternately to charge and discharge a capacitor, was chosen for its simplicity and consequent reliability. Modifications to the basic circuit were necessary because of the imperfect operation of diodes used as a switch.

This paper discusses the imperfections of diodes as switches and shows how these are compensated to obtain the high degree of linearity and stability.

The Basic Circuit

The diode pump uses each cycle of input frequency to remove a fixed charge from a storage capacitor. The integral of these charges is a current proportional to frequency which is balanced against a current derived from the tap of a linear potentiometer. Any current unbalance is used to control automatically the potentiometer shaft. At balance the position of this shaft is an accurate measure of the input frequency. The basic circuit is shown in Fig. 1. The operation of this circuit at balance may be explained very simply if the diodes D_1 and D_2 are assumed to be perfect switches.

The driving circuit provides currents of about 1 ma (milliampere) which alternately charge and discharge C_1 during each cycle of input signal. The charging current i_1 flows through C_1 and D_1, the discharging current i_2 through C_2, D_2, and C_1. The voltage through which C_1 may swing is limited by diodes D_3 and D_4 to a peak-to-peak value of V_1. Each discharge current takes a charge $Q_1 = C_1V_1$ from C_2. In one second charge, fQ_1 is removed from C_2 where f is the input frequency. This is an average current of fQ_1 amperes. The voltage across C_2 is held at zero by the injection of an equal current through R_1. This current is $i_3 = v/R_1$ where v is the voltage at the tap of the potentiometer.

Hence, at balance,

$$v/R_1 = fC_1V_1$$
$$v = C_1R_1V_1f \qquad (1)$$

In order for v, and therefore the potentiometer shaft rotation, to be proportional to f it is necessary that $C_1R_1V_1$ be constant for all frequencies and temperatures within the specified ranges. C_1 and R_1 are independent of frequency in the audio range and are chosen with equal and opposite temperature coefficients. V_1, the voltage swing of C_1, must be stabilized.

However, diodes which act as perfect switches were assumed during the derivation of equation 1. Real diodes conduct reverse leakage currents and have forward voltage drops. It is necessary to examine the basic circuit to see what effect these diode imperfections may have on its operation.

Diode Imperfections

Silicon junction diodes have been used in the final circuit because, in the OFF condition, they are nearly perfect switches with leakage currents of about 10^{-9} amperes. In the ON condition, they are poor switches requiring about 0.6-volt forward drop in order to conduct 1 ma.

Because of this large forward drop and because of the rapidly increasing diode resistance with reduced forward voltage, the basic circuit will not have the same initial conditions for each charging and discharging current throughout the 10-to-1 range of frequency. Consider only the discharging half of one cycle. When, at the end of a charging cycle, the capacitor C_1 (see Fig. 1) is charged to voltage V_1, V_a will be approximately

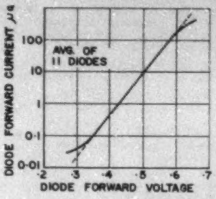

Fig. 2. Silicon diode forward characteristics

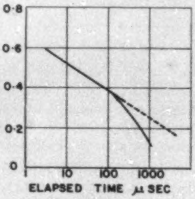

Fig. 3. Decay of V_a

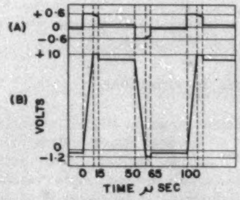

Fig. 4. Required waveforms

A—Pump waveform, V_a
B—Input waveform

+0.6 volt. This voltage will decay at a a rate,

$$dV_a/dT = i_f/C_1 \tag{2}$$

where i_f is the forward current through D_1. Below 100 μa (microamperes), the forward current is given by the expression[2]

$$i_f = i_s(e^{v/CKT} - 1) \tag{3}$$

where

$v = V_a$ the forward voltage
KT = energy equivalent of temperature
C = a constant dependent on diode construction
i_s = theoretical saturation current

Fig. 2[3] shows this current–voltage relation for 11 typical silicon diodes.

From equations 2 and 3 it can be shown that V_a decays logarithmically. This is illustrated in Fig. 3 which is a plot of V_a against log (time). As V_a falls below 0.3 volt surface leakage, not accounted for in equation 3, begins to come into play. Since i_f is greater than equation 3 states, V_a falls more rapidly than is predicted by equations 2 and 3.

The linear relation between v, the potentiometer voltage, and f, the input frequency expressed in equation 1, does not hold because of the slow decay of V_a. This voltage, at the start of a discharge cycle, will be somewhere between +0.5 and +0.2 volt depending on the time which has elapsed since the charging current. The discharging current will therefore remove a charge in the range C_1 $(V_1 - 0.5)$ to C_1 $(V_1 - 0.2)$ from C_2, the exact charge being dependent upon the frequency.

Compensation for Diode Imperfection

The charge removed from C_2 has been made constant by ensuring that V_a returns to a near-zero voltage at a fixed time after each edge. The desired waveform is shown in Fig. 4(A). It is obtained by arranging the limiter so that within 5 microseconds after each charging or discharging the input voltage will fall about 0.6 volt. The necessary waveform is shown in Fig. 4(B). The 0.6-volt step is obtained from the circuit of Fig. 5.

Immediately upon the application of a 1-ma step input current the diode of Fig. 5 conducts almost all the current and V_{in} rises to 0.6 volt. As the series resistance of the choke is low, the current in L rises linearly at the rate V_{in}/L amperes per second. The diode drop changes little until the choke is conducting nine tenths of the current. This occurs in about 4 microseconds afrer which V_{in} falls rapidly to 10 millivolts. A silicon diode is used to form the step in order that its height will vary with temperature in the same way that the drop across the pump diode varies. A 2.7-K resistor is required to damp the ringing which would otherwise occur between the diode capacitance and the choke.

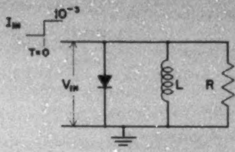

Fig. 5. Step-forming circuit

This circuit is included in the final pump circuit shown in Fig. 6.

Temperature and Supply Voltage Compensation

Two minor additions to the basic circuit ensure that the input voltage swing is largely independent of temperature and that the supply voltage variations will have little effect on the linearity. The first objective is achieved by adding two extra silicon diodes into the reference supply. When this is done, the discharging current reduces the voltage across C_1 by the reference supply V_1 plus the voltage drop across diodes *3*, *4*, and *5* less the drops across diodes *2*, *7*, and *8* as may be seen from the diagram of the input waveform in Fig. 4(B). Thus the voltage swing will vary with temperature only as the difference between diode drops varies with temperature. This is a second-order dependency.

By using the same supply voltage for the reference as for the linear potentiometer, the effect on linearity of variations in this supply is largely eliminated. Only a fraction of any change in supply voltage is reflected as a change in the constant of proportionality of shaft position to frequency. This fraction is the ratio of the difference between diode drops to the total voltage swing and is less than 0.008, and is probably less than 0.004. The supply voltage is stabilized to ±5%.

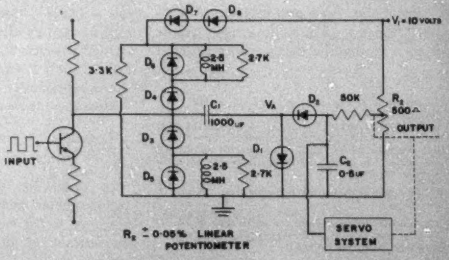

Fig. 6. Final circuit diagram

Detector

In order to measure the range of frequencies at 2–20 kc, C_1 and V_1 were arbitrarily chosen equal to 1,000 micromicrofarads and 10 volts. This makes $R_1=50\,K$ for a full shaft rotation representing 20 kc. Hence the maximum current flowing into the storage capacitor is $V_1/R_1=200$ μa. In order to maintain balance to ±0.1% of full scale, the servo system must operate with a signal of less than ±0.2 μa. The detector used is the modulator described by Moody[3] which can reliably detect signals of ±0.1 μa.

Conclusions

With reference again to equation 1

$v=C_1R_1V_1f$

Now

$v=rV_1$

where $r(<1)$ represents the fractional rotation of the potentiometer shaft. Thus

$r=R_1C_1f$

with the errors noted in the two preceding sections.

The circuit shown in Fig. 6 was built using a linear potentiometer which was calibrated with a potential divider to ±0.01% and tested over a frequency range of 2 to 20 kc as measured on an electronic counter to ±1 cycles per second. The shaft position was linearly proportional to input frequency with an accuracy of ±0.04% of full scale at any temperature and the constant of proportionality changed by 0.1% between −55 C and +55 C.

Summary

By accurately controlling the conditions at the start of each discharging current, by compensating for temperature variations in the critical limiting and current-defining components, and by balancing supply voltage variations, an instrument has been constructed which will automatically convert frequency into shaft position with an accuracy of ±1.0%.

Discussion

P. M. Thompson (Defence Research Board, Ottawa, Ont., Canada): Mr. Mitchell shows that it is possible to achieve a linearity of ±0.1% with a diode-pump frequency-measuring circuit if care is taken to compensate it for diode imperfections. In his treatment he considers the leakage current and the forward voltage drop. However, at high switching speeds the effects of diode turn-off time must become important. The turn-off characteristic must bear directly on the fall of voltage of the pump waveform V_a [Fig. 4(A)] during the time between the end of the charging cycle and the collapse of voltage across the 2.5-millihenry inductors shown in Fig. 6. If this is not well controlled, it will be difficult to define the desired potential step due to D_5 and D_6 (Fig. 6) necessary to reduce the potential at V_a to 10 millivolts or less.

J. Mitchell: Mr. Thompson's point about switching speeds is a good one. In fact, different types of diodes may show markedly different characteristics when forward current is plotted against voltage and, therefore, the decay of V_a will vary from type to type. Furthermore, the diode capacitance attenuates the effect of the collapse of voltage across the inductor. I think, however, that the diode turn-off characteristic, in the usual sense of the term, would only indirectly (in that it may imply a greater or lesser effective diode capacitance) affect the circuit's operation.

The maximum frequency which may be measured by this circuit will be determined first by the currents available to charge and discharge C_1 (Fig. 6) and by the value of C_1 itself, and second by the time that V_a must be allowed to decay naturally if the collapse of voltage across the inductor is to be entirely effective in reducing V_a to the same value (±10 millivolts) near zero every time in spite of the diode capacitance. The first mentioned time may, in theory, be made very small. It is doubtful if the second can be reduced below 4 to 5 microseconds. Therefore, there is an absolute frequency limit of about 100 kc. The practical frequency limit is undoubtedly lower, probably no greater than 40 to 50 kc.

Organic-Moderated Reactors for Central Station Power

W. E. PARKINS
NONMEMBER AIEE

E. F. WEISNER
NONMEMBER AIEE

THE CONCEPT of a power reactor which would use an organic fluid as the moderator and coolant has been considered an attractive possibility for several years. This concept suggested itself because of the many physical properties of organic fluids which are superior to those of water when used as the moderator in a nuclear reactor.

In its simplest form an organic-moderated reactor would utilize a tank containing the core and through which the organic fluid would be pumped to remove the heat being generated. The fuel would be in the form of an array of solid elements within the core tank, and appropriate control elements would be distributed for startup, shutdown, and regulation of the reactor power.

As in the case of water-moderated reactors, the fuel could not be natural uranium but would of necessity contain some form of enrichment. The nuclear properties as they affect the reactor performance are very similar for water and for organic fluids of interest. The principal difference between a water-moderated reactor and an organic-moderated reactor in the simple description just given, would be in the design of the core tank. The organic fluid, being of lower vapor pressure, would be operated at the same or higher temperatures, while using a vessel designed for about one tenth the pressure which would be required for a water-moderated system.

Choice of Organic Fluid

In choosing a suitable organic fluid to serve as the moderator-coolant in a power reactor, it was necessary to investigate the stability of many different hydrocarbon compounds. These

Paper 58-1272, recommended by the AIEE Nucleonics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted July 16, 1958; made available for printing September 9, 1958.

W. E. PARKINS and E. F. WEISNER are with Atomics International, Division of North American Aviation, Inc., Canoga Park, Calif.

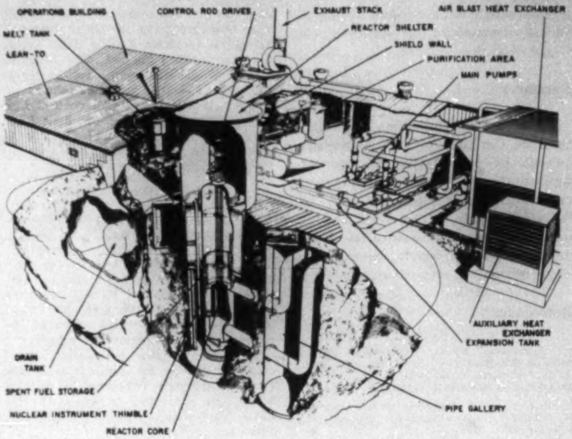

Fig. 1. OMRE facility at the National Reactor Testing Station

investigations included both stability against thermal, or pyrolytic, decomposition and stability against radiation decomposition. The results of many measurements carried out at elevated temperatures in the laboratory and in special exposures with gamma-ray, electron, and neutron radiation have indicated the polyphenyl compounds to be the most suitable class. These compounds are formed by linked aromatic rings. Of greatest interest are diphenyl, consisting of two rings, and the ortho-, meta- and para-isomers of terphenyl, based on the different linkages of three aromatic rings.

The diphenyl and commercial mixtures of the terphenyl isomers are available at prices of less than 20 cents per pound. During operation of the reactor, it is necessary to add new organic material because, while these compounds are quite stable, they do gradually decompose under the influence of the radiation present in the reactor core.

Advantages of an Organic Fluid as Reactor Moderator

Because of the lower vapor pressures, organic fluids may be used in the 500–700 F (degrees Fahrenheit) range without the requirement of a high-pressure system. Diphenyl boils at 492 F at atmospheric pressure, and its vapor pressure at 700 F is 112 psia (pounds per square inch absolute). The terphenyls boil in the neighborhood of 700 F at atmospheric pressure. Practical operating pressures for organic reactors appear to be in the 50- to 300-psia range.

Another paramount advantage for organic fluids is the low corrosion rate. Standard engineering materials such as low-carbon steels and aluminum may be used throughout the reactor and external coolant system, since their corrosion rate with organic fluids is essentially zero. The corrosion rate with uranium and other nuclear fuels is very low, which is important since it means that few radioactive fission products would get into the coolant stream even if the fuel cladding should fail. From the safety standpoint it is to be noted that no exothermic chemical reactions can occur under any possible conditions between the organic fluid and any materials used in the reactor system.

The induced radioactivity in hydrogen and carbon as a result of exposure to the neutrons in the reactor core is negligible. This is important since it results in minor shielding requirements for the external coolant system and greatly eases maintenance problems. In this respect organic fluid is superior to water, which contains oxygen and requires special shielding of the external system during reactor operation.

Problems Associated with Organic Fluids

The principal problem associated with the use of organic fluids in nuclear reactors is the radiation decomposition. The interaction between the nuclear radiation and the organic, results in the production of hydrogen and light hydrocarbons which appear as gases and must be vented. In addition, higher molecular weight or polymeric materials are formed and must be gradually removed by a purification system to maintain their concentration at some suitable equilibrium value. As will be mentioned later, no difficulty has been experienced from the fouling of heat transfer surfaces by the deposition of these high polymers. In the operating range of interest they are maintained in solution in the organic fluid. Similarly, in the operating range of interest there has been no significant contribution to the organic decomposition rate due to pyrolytic effects.

Although most organic materials are flammable, the polyphenyls are not particularly difficult to handle. They have rather high spontaneous ignition temperatures in the neighborhood of 1,000 F. Ordinary refinery practices and precautions are adequate to insure against fires. Because of their low vapor pressure, handling of the polyphenyls at ambient temperatures presents no particular health hazard. Proper ventilation must be provided in locations where it is necessary to work with these fluids at elevated temperatures.

Another disadvantage of these organics is the fact that their melting points are somewhat above room temperature. Diphenyl melts at 157 F, while the commercial mixtures of terphenyls melt in the range of 150–300 F. As a result, it is necessary to provide steam tracing or some form of electric heating for the piping and other components of the organic system.

Design of the OMRE

In order to test the use of an organic fluid used as the moderator-coolant in a reactor, the Atomics International Division of North American Aviation entered into a contract with the Atomic Energy Commission in mid-1955 for the construction and operation of the organic-moderated reactor experiment (OMRE). While many aspects of the organic fluid as used in a reactor were to be investigated, the principal factor to be studied was the organic decomposition and its effect on the over-all reactor performance. As a result, the OMRE was designed for a variety of operating conditions up to a maximum thermal power of 16 mw (megawatts). No provision was made for the generation of electric

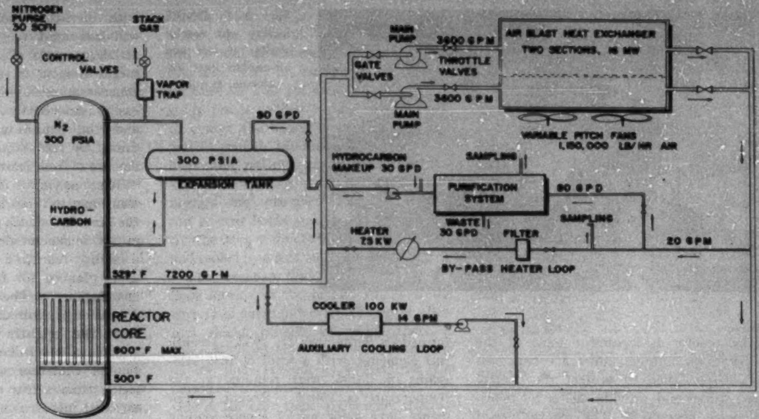

Fig. 2. OMRE schematic flow diagram

power. The reactor heat was dissipated to atmosphere in air-cooled exchangers.

The OMRE was constructed at the National Reactor Testing Station near Idaho Falls, Idaho. Installation was completed in May 1957, and the experimental program has been in progress since that date. The following sections give a brief description of the OMRE design.

Reactor

Fig. 1 shows a cutaway view of the OMRE facility. The reactor vessel is of a mild alloy steel, $4^1/_2$ feet in diameter, 28 feet tall, with a wall thickness of 1 inch. The reactor core is located in the lower region of this vessel.

Because of its availability a plate-type fuel element with fully enriched uranium in the form of UO_2 in a stainless-steel matrix and clad by stainless steel was used. The UO_2 and stainless-steel matrix is 0.020 inch thick and the cladding 0.005 inch thick. The spacing between plates for passage of the organic fluid is 0.134 inch. Each element is assembled from 16 fuel plates enclosed in a rectangular box 2.8 by 2.9 inches in cross section. The uranium fuel is loaded into each fuel plate over an area 36 inches high by 2.5 inches wide. The rectangular boxes comprising the elements are positioned on a 4.5-inch-square lattice and are supported by an upper and a lower grid plate. Thirty-six fuel-element positions are available and an extra position is reserved for an antimony-beryllium neutron source.

A 2-inch-thick thermal shield is located inside the reactor vessel and outside of the fuel-element region. The organic coolant enters the reactor vessel at a plenum below the core. It then flows upward between the fuel plates and discharges into the space between the fuel-element boxes. After flowing downward around the outside of the fuel elements, it flows upward between the thermal shield and the reactor tank and discharges into a 14-foot-deep pool above the reactor core.

The OMRE is controlled by 12 control rods symmetrically located between fuel elements. These rods consist of $1^1/_4$-inch-diameter steel tubes loaded over a 36-inch length with compacted boron-carbide powder. The 12 rods are hung in pairs from six hanger rods and are driven through rack-and-pinion drives. All rods perform the double function of control and safety, with one pair being driven through a differential gear to provide both fast regulating action and slow shim action. For rapid shutdown the rods are released by a ball-type latch, and a kick-off spring insures downward acceleration.

Process System

A schematic flow diagram for the OMRE is shown in Fig. 2. Nitrogen cover gas at a nominal operating pressure of 200 psia is used over the free organic surface in the reactor vessel. A continuous purge of the nitrogen removes the hydrogen and light hydrocarbon gases formed by the organic decomposition. These gases are diluted by the building ventilation system and vented out the exhaust stack.

The cooling system circulates 7,200 gpm (gallons per minute) of organic fluid from the reactor through the air-cooled heat exchanger by means of two centrifugal hot-oil pumps operating in parallel. A small auxiliary coolant loop rated at 100 kw is provided to remove afterglow heat from the reactor during shutdown, when the main coolant loop is inoperative. The auxiliary loop uses a spray cooler as its heat sink. A batch-type purification system is incorporated to remove the high polymers formed in the organic fluid. A still is used to separate the polymer, with the undamaged organic being returned to the primary circulation system together with the necessary makeup material through the expansion tank. This expansion tank is necessary to provide for the change in volume which occurs in the organic during changes in system temperature. In order to measure the heat transfer properties of the organic fluid being circulated in the primary system, a special by-pass loop is incorporated. This loop contains a heater and appropriate means for temperature and flow measurement to permit determination of the heat transfer coefficient.

With the exception of the reactor vessel, the entire organic system is made from carbon steel. All components and piping can be preheated to a temperature of 350 F. Sixty-cycle induction heating is used on the vessels and piping. The pumps and valves are traced with heating cable, and the air-blast heat exchanger is provided with an oil burner.

Plant Layout

The OMRE was constructed as a minimum cost facility. The general layout is shown in Fig. 1 and the completed installation is shown in Fig. 3.

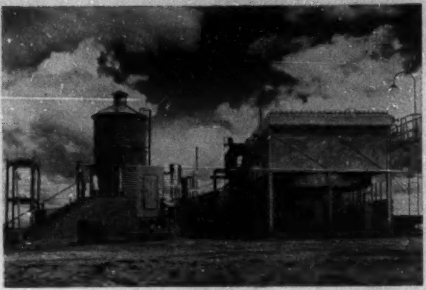

Fig. 3. OMRE facility with reactor shelter at left and air-cooled heat exchanger at right

The reactor is located outside of the operations building under a corrugated-sheet-steel shed to protect the control rod drives and provide shelter for maintenance personnel. The reactor vessel is for the most part buried underground. Inlet and outlet coolant pipes pass through tunnels and to ground level at the operations building. The pumps, purification system, and other auxiliary equipment are located in the process area. The air-cooled and auxiliary heat exchangers are located out-of-doors.

The process area is separated from the control room by a 2-foot-thick wall of ordinary concrete. Valve mechanical operators pass through this wall. The control room houses the operator's console, recording instrumentation, and electric switchgear. Adjacent to it is a separate service area containing the nitrogen-gas supply system and the organic melting and filling system.

Results of the OMRE Operation

As part of the preoperational testing, many portions of the OMRE installation were separately checked. The 60-cycle induction-heating equipment for the piping primary system was operated and found to be very satisfactory. Kerosene was first used in place of the organic to prove out the circulation system. The response of the control-safety rod drives was determined to be satisfactory. The methods for fuel handling were checked out, as well as the operation of the purification and other auxiliary systems.

The organic fluid chosen for first use in the OMRE was Santowax-OM, a commercial mixture principally containing the ortho- and meta-terphenyls together with some diphenyl. After the reactor and primary system were filled with this material and the circulation tests completed, the critical experiment was performed on September 17, 1957. Twenty fuel elements, with a total of 16.4 kilograms of U-235, were required at the temperature of 250 F. Recent experiments have made use of a core loading of a total of 31 fuel elements. Some of these elements are instrumented with thermocouples to provide temperature measurements during operation.

Experiments were carried out to calibrate the control rods, to measure neutron flux distributions within the core, and to determine the various coefficients of reactivity. The reactor performed well and there was no significant unexpected behavior.

Special attention was given to measurement of radiation levels. Trace amounts of inorganic impurities were determined to be present in the coolant but their contribution to the radiation levels was rapidly decreased as a result of operation of the purification system. These impurities, which include sodium, manganese, chlorine, and copper were largely removed together with rust, metal filings, welding slag, and other impurities present within the primary system. Actual measurements of radiation levels at various points during power operation have confirmed the most optimistic predictions. The highest radiation level in the process area was 80 milliroentgens per hour at the surface of the 10-inch primary pipes, while operating at a power level of 10 mw. The radiation level in the center of the process area under these conditions was 13 milliroentgens per hour. Such levels permit access by maintenance personnel on an almost continuous basis.

The principal matter for investigation has been the rate of polymer formation as a function of various operating conditions. The equilibrium polymer content in the circulating organic has been varied up to 30%. The rate of polymer formation was determined to decrease with increasing polymer concentration and has most recently been measured at $2^{1}/_{4}$ pounds of polymer formed per megawatt-hour of operation at the 30% concentration. This material has been easily removed by the purification still and the equilibrium condition maintained by the addition of an equivalent amount of fresh Santowax-OM.

The polymer formation rate just mentioned is known to be about twice the amount which would be obtained in an organic-moderated reactor using a slightly enriched uranium fuel, such as is planned for future power reactor installations. The reasons for this difference is primarily due to the fact that the slightly enriched uranium absorbs a much larger fraction of the gamma radiation present in the core region than is true of the special highly enriched fuel elements being used in the OMRE. All estimates have shown that with current prices for the organic, the contribution of the cost of makeup material to the final cost of electric power produced is less than 1 mill per kw-hr (kilowatt-hour), based on the experimental results which have now been obtained.

As another extremely important matter related to the polymer formation in the organic, no evidence of surface fouling has been observed in the OMRE. Such an effect would have been detected by the fuel-element thermocouples or the by-pass heater loop. These results verify earlier measurements of various organic fluids circulated in in-pile loops at the materials testing reactor.

The operation of the OMRE has shown the organic-moderated type of reactor to be a practical concept. No unusual difficulties have been encountered. The low radiation levels have verified the feasibility of contact maintenance during operation on all parts of the system except the reactor core. A simple type of purification system has been shown to be adequate, and the rates of polymer formation and gas evolution are nominal. The lack of any surface fouling effect has been of special significance in assuring continued high performance of the reactor system.

OMR for the City of Piqua

At the time of the request by the Atomic Energy Commission for proposals for the second round of demonstration reactors, the city of Piqua, Ohio, proposed the construction of an organic-moderated reactor (OMR) for its municipal system. A contract between the Atomic Energy

Vol.
Pt. 1
195

Commission and Atomics International for the engineering and construction of this plant has recently been completed. Preliminary design is in progress and a schedule has been established leading to completion of construction during 1961.

The necessary turbine equipment is available at the Piqua site, and it is required that the reactor system provide steam at the rate of 162,000 pounds per hour, at 450 psia and 550 F steam conditions. The reactor installation is essentially sized for a plant of 12.5 gross electrical mw, or 11.4 net electrical mw.

In addition to the work being carried out on the OMRE, there has been a research and development program sponsored by the Atomic Energy Commission to investigate the properties of organic fluids and to develop components suitable for organic-moderated reactor systems. Additional development work will be carried out specifically in connection with the plant being designed for the city of Piqua. In the paragraphs which follow, a description is given of a reactor of the size required for Piqua. The features described are essentially those now planned as a part of the preliminary design in preparation.

REACTOR

Fig. 4 shows a vertical section of the reactor. Certain of the features are similar to those incorporated in the OMRE. The reactor vessel is of low-carbon steel, has an inside diameter of 6 feet, an over-all height of 25 feet, and a wall thickness of 1 inch. It is designed for a maximum operating pressure of 300 psi gage at 650 F. A guide pin is welded to the bottom head to center the vessel during installation and to provide lateral support. Coolant inlet and outlet nozzles penetrate the vessel above the reactor core. Other nozzles are provided for the control rod electric leads and for thermocouples. At the top, a reinforced head is bolted and sealed by a soft metal gasket.

The reactor tank is located below floor level. In the neighborhood of the core it is surrounded by the outer thermal shield, outside of which there is thermal insulation and a carbon-steel cavity liner serving as a form for the concrete foundation. Immediately inside of the core tank is the inner thermal shield which is supported on a flange welded to the vessel at an elevation above the core. Attached to this inner thermal shield are the upper and lower grid plates, each approximately 6 inches thick. These gridplates are pierced by 69 holes appropriately to support and locate the fuel elements.

The organic fluid planned as the moderator-coolant in the Piqua OMR is Santowax-R. This material consists of a commercial mixture of the three terphenyl isomers. It melts in the range of 140 to 290 F and boils at atmospheric pressure at a temperature of about 700 F. It serves not only as the moderator and coolant, but as the reflector in the region surrounding the core. In addition, a 15-foot-deep pool of organic above the core provides shielding in that region. The organic enters the reactor vessel above the core, then flows downward between the inner thermal shield and the core tank wall. From the lower plenum it flows upward through the fuel-element assemblies as well as through the spaces between fuel elements into the upper pool. Nominal temperature conditions for the organic fluid are 550 F inlet and 600 F outlet. The total flow rate is 11,000 gpm.

FUEL ELEMENT

The reactor fuel is slightly enriched metallic uranium with stabilizing alloying. Required enrichment is 1.8% of U-235 in the uranium. Each fuel element consists of finned aluminum-clad uranium plates contained within a square steel box, as shown in Fig. 5. The fins are of triangular cross section and run parallel to the direction of coolant flow. In addition there are fins of rectangular cross section which extend across the coolant gap to maintain the spacing between fuel plates. The fuel elements are supported in the lower grid plate and are free to expand upward through the locating hole in the upper grid plate. The fuel element boxes are approximately 5.25 inches square and are located on a square array 6 inches between centers. The length of the uranium-loaded section in the fuel plates is 4.5 feet. An orifice at the lower end

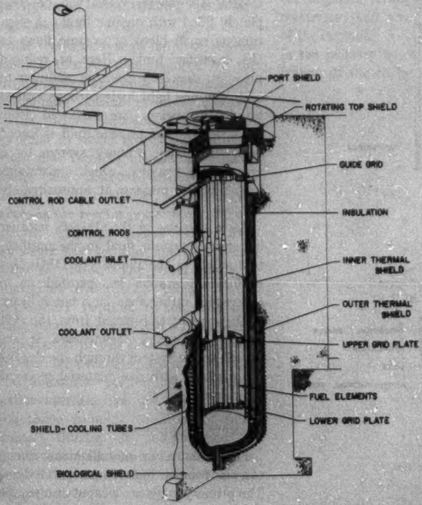

Fig. 4 (left). Reactor for 11.4-mw plant

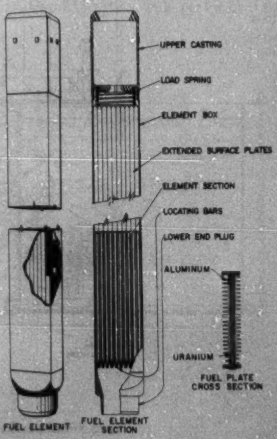

Fig. 5 (right). OMR fuel element

of each fuel element is used to regulate the flow so that the maximum surface temperature within that element does not exceed 750 F.

Control-Safety Elements

Six control elements regulate the reactor and provide for emergency shutdown. The poison rod, drive, and position indicator of each control element are arranged in a compact assembly that can be inserted into a standard fuel-element position in the core. These elements are of the "magnetic jack" type in which movement of the rod is achieved by alternate energizing of a series of magnets to hold, lower, or raise the poison rod in small step increments. The movable portions are sealed within a stainless-steel tube and the only outside connection is by means of the electric leads. The poison rod is released to fall by gravity into the core region whenever the current supply to the hold magnets is interrupted.

Fuel-Handling System

The principal components of the fuel-handling system include the reactor top head, the top shield, the fuel cask, the cask carriage, and the storage areas for new and irradiated fuel. The general arrangement is shown in Fig. 6.

Access to the core tank is provided by loosening the flange bolts which fasten the upper head, and raising this head slightly so that it may be attached to and rotated with the top shield. The shield is supported on a circular bearing which allows rotation to any desired angle or position. The top shield assembly contains a plug which fills a port in the shape of a radial slot in the top shield. By properly rotating the shield, the access port may be brought over any particular position within the core.

A lead-shielded cask mounted on a carriage is then moved to the top shield and located over the desired position. Fuel elements may be withdrawn into the cask by means of a latching assembly which extends down through the cask. The escape of organic vapors during this period is minimized by a sliding assembly over the port of the top shield. Fuel-changing operations would normally be carried out with the organic temperature in the neighborhood of 350 F. It should be noted that the organic fluid is quite opaque and these manipulations must be carried out without the aid of visual observation in the core tank.

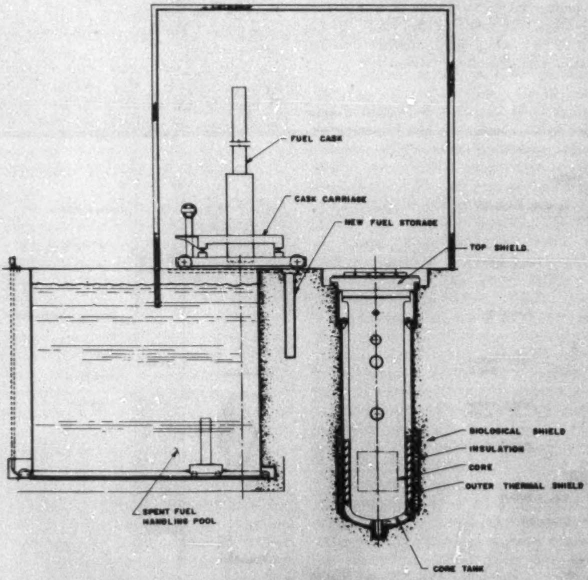

Fig. 6. Fuel-handling arrangement for OMR

After an aligned element has been withdrawn into the cask, the carriage can be traversed over an adjacent pool of water used as a storage facility. Fuel elements may be lowered into this canal and handled in a rack arranged to move along its floor. After a period of storage for the decay of afterglow heating, the fuel elements may be loaded into a cask for shipment to a chemical processing plant.

Primary Coolant System

The primary coolant system is divided into two parallel loops. A simplified flow diagram showing one of these loops is given in Fig. 7. From the reactor the coolant flows through a pump, a superheated, and an evaporator, and returns to the reactor. Each pump is a centrifugal unit of the horizontal split-case type with mechanical seals. The superheater and evaporator are shell and tube units horizontally mounted and constructed of mild ssteel. Blocking valves, not shown in Fig. 7, may be used to isolate either loop near the reactor. These valves and others in the system are of the cast-steel back-seated packed-stem type. Coolant lines are seamless carbon-steel pipe. Equipment such as valves, pumps, and other components which require maintenance are flanged into the system with seals made of soft iron gaskets.

In contrast to the arrangement on the OMRE, the reactor vessel will be completely filled with organic fluid. A continuous small bleed of organic flows to the degasifier tank. Here at reduced pressure, dissolved gases, in addition to hydrogen and light hydrocarbons formed by decomposition, are removed from the system. The organic fluid is forced back into the primary system by a pressurizing pump which maintains proper system pressure at approximately 120 psia.

As in the case of the OMRE, another line carries organic fluid to the purification still. In the Piqua-type OMR this purification system is operated on a continuous rather than on a batch basis. High polymer is rejected from the still bottoms. Organic condensate is returned to the system through the degasifier together with new material required for makeup.

Plant Arrangement

Fig. 8 shows an over-all arrangement of a plant similar to the Piqua installation. The primary loops are located in separate

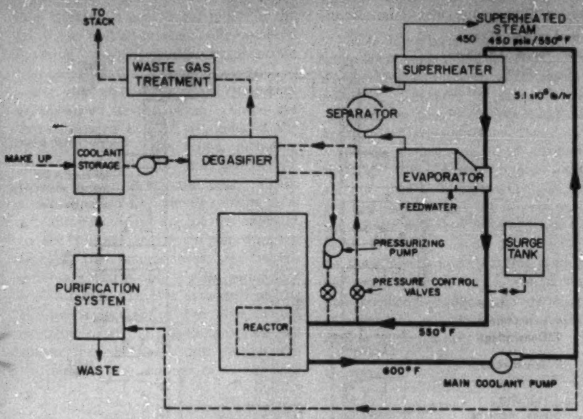

Fig. 7. OMR basic flow diagram

rooms shielded with approximately 2 feet of ordinary concrete. Suitable ventilation control is provided these areas. Steam at 450 psia and 550 F is carried from the superheaters to the turbine located in an adjacent room. A regenerative steam cycle incorporating three stages of steam extraction for feedwater heat is employed. There is a deaerator in the 40-psi extraction line. A conventional a-c alternator is used to generate the 12,500 kw of gross electric power. Feedwater is returned to the evaporator at 337 F. Dry steam leaves the separator before entering the superheater at 448 F.

The control system adjusts reactor power output to that required by the turbine generator while simultaneously maintaining steam pressure constant at the turbine throttle. A signal proportional to steam flow is taken from a steam flow recorder on the main steam header and inserted directly into a neutron flux controller. This signal serves as the reactor power level primary control. The same signal is taken from the steam flow recorder and routed to a power computer. The power computer determines the reactor coolant outlet temperature required to maintain constant steam pressure and sends a signal proportional to this desired temperature to the temperature-recorder-controller. The automatic portion of the control system operates over the power generation range from 15 to 110% of rated power. Startup is accomplished by manual manipulation of the control elements using the nuclear startup instrumentation.

OPERATIONAL AND ECONOMIC ASPECTS

As has been apparent from the foregoing discussion, no steel containment vessel is planned for housing the reactor installation. Characteristics inherent in the design of an OMR make it unnecessary to provide special housing of this nature to prevent the dispersal of radioactivity as a result of any conceivable accident. The principal factors contributing to this inherent safety are the absence of potential chemical reactions, the negative temperature coefficients of reactivity, and the low vapor pressure of the coolant. A sudden loss of pressure in the primary system does not produce boiling of the coolant, and it is possible to design the system to maintain core cooling in spite of any accidental condition.

As was pointed out for the OMRE, it is expected that maintenance of the OMR plant will be straightforward. All components, with the exception of the core, should be accessible. It has been calculated that even a fuel-cladding break will result in small increase in the radiation levels. Again, the purification and degasification systems serve to remove such accidental fission product contamination on a continuous basis.

The capital charges for the second or subsequent complete 11.4 net electrical mw OMR plants are estimated to be approximately $500 per net installed kw or $5,700,000 total. Treating the capital investment as an annual charge of 15% of the total, and assuming an 80% load factor, the capital investment contributes 9.5 mils per kw-hr to the total power cost.

Annual fuel costs depend to some extent on the fuel exposure time and on the load factor. In this reactor the average exposure time is expected to be from 3,000 to 4,000 megowatt-days per per ton. The load factor is estimated at from 60–80% depending upon the application. Within these ranges the fuel cost will be between 5.4 and 6.3 mils per kw-hr. This figure includes the burned-fuel cost, fuel fabrication, processing, shipping, inventory costs, and credit for plutonium produced.

At this stage of development the exact cost for plant maintenance is difficult to predict. Based upon information available it is estimated that the costs for operation, maintenance, and organic makeup will total 2 to 3 mills per kw-hr.

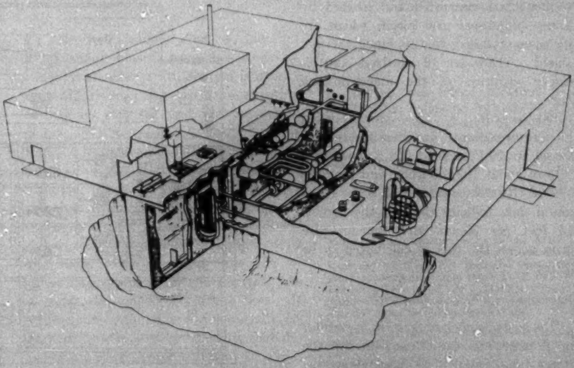

Fig. 8. Cutaway view of 11.4-mw OMR plant

The total cost of power from this plant is therefore in the neighborhood of 18 mills per kw-hr. Reductions in this figure are expected as further advances are made in the technology of organic-moderated reactor plants.

OMR for Large Central Station Plant

The organic-moderated reactor concept, while very suitable for small, inexpensive, power-reactor installations, is not limited to plants of small output. Engineering studies and preliminary designs have been carried out for plants of 50, 100, and 150 net electrical mw output.

These designs have all been based on the use of a single reactor in each plant, and no limitation has yet been foreseen in the maximum thermal power which might be obtained from a single reactor installation. The lack of such a limitation in the maximum output is in part due to the fact that the primary system, and hence reactor vessel, operates at a relatively low pressure.

To give an example of a large OMR central station plant, the following paragraphs describe some of the features recommended for a plant of 150 electrical mw.

REACTOR

A vertical cross section of the reactor is shown in Fig. 9. As is apparent, except for size the reactor design is very similar to that described for the Piqua-type OMR. The reactor vessel is approximately $14^1/_2$ feet in diameter and 49 feet high. The active core region is 10 feet in height, 11.3 feet in diameter, and contains 325 fuel elements. These elements are supported and located by lower and upper grid plates which are in turn attached to the inner thermal shield. There are 16 unitized control-safety elements of the magnetic-jack type.

Santowax-R is the recommended moderator-coolant. It enters the reactor vessel at 550 F, exits at 618 F, flows at a rate of about 100,000 gpm, and removes a total thermal power of 555 mw. Maximum flow velocity through the core is 15 feet per second and the pressure drop across the core is calculated to be 35 psi.

PROCESS AND STEAM SYSTEMS

The organic-coolant system is similar in principle to that described for the Piqua-type OMR. It uses, however, six parallel heat-removal loops. Each

loop contains a centrifugal pump in the hot leg as well as automatically operated blocking valves capable of isolating that loop from the others.

Fig. 10 is a plan view of the equipment arrangement in the plant. There are three loops on each of two sides of the reactor. These three loops, including their evaporators and superheaters, are housed in a single process room. Tanks and equipment for organic-coolant storage and purification are located adjacent to the process area. On the opposite side of the process area, the turbogenerator and steam system equipment are installed. In this arrangement the turbine is located on the floor at the elevation of the top of the reactor. An extension of this floor forms the concrete shielding at the ceilings of the process areas.

A total of 320,200 pounds of steam per hour are produced at 415 psia, 550 F. The turbine is a high-speed unit having a gross capability of 162,000 kw and using $1^1/_2$ inches of mercury exhaust pressure. Three feedwater extraction stages are provided.

OPERATIONAL AND ECONOMIC ASPECTS

The building housing the OMR installation is of conventional construction and no special containment vessel need be provided. The inherent safety features described for the Piqua-type OMR also apply to this larger plant.

In regard to costs, it is estimated that capital investment required for the 150-mw OMR is approximately $250 per net installed kw. Fuel costs on the same basis described for the Piqua-type OMR are 4–5 mills per kw-hr. Based on these figures and including appropriate charges for operation, maintenance, and terphenyl makeup, the total cost of power is estimated to be approximately 10–11 mills per kw-hr.

Summary

The basic experiments on the properties of organic fluids and the recent operation of the OMRE have shown the concept of a nuclear reactor moderated and cooled by an organic fluid to be practical. This type of reactor appears to have particular advantages for central station application because of the adequate steam conditions obtainable and the excellent safety characteristics of OMR plants. Capital costs are low because of the nominal operating pressures required and because conventional materials, together with conventional field fabrication techniques, can be used throughout the installation.

Work on design of the 11.4 net electrical mw OMR for the City of Piqua, Ohio, is in progress. New information is currently being obtained as part of the research and development being carried out for the organic reactor program.

The concepts developed for the Piqua-type OMR can be applied to much larger central station plants. There appears to be no basic limitation in the size of such plants.

Present estimates indicate the cost of power to be comparable to, if not lower than, that obtainable from other types of nuclear plants. Actual performance of large OMR plants, as well as of other types, must await the additional experience which will follow when such plants are built and operated.

Theory of Transient Build-up in Avalanche Transistors

W. SHOCKLEY
NONMEMBER AIEE

J. GIBBONS
NONMEMBER AIEE

Synopsis: It is found that an avalanche transistor biased into the negative resistance range will deliver an exponentially increasing current into a capacitor connected between the emitter and collector. For a uniform base layer of width W, minority carrier diffusion constant D, emitter efficiency γ, collector capacitor C_c, load capacitor C, and avalanche multiplication M, the current builds up as $\exp \lambda t$ where

$$\lambda=(D/W^2)[\cosh^{-1} \gamma MC/(C+C_c)]^2-\nu$$

where ν is the reciprocal of the minority carrier lifetime. The time required for a voltage drop from near breakdown voltage to about 89% of breakdown voltage is about $W^2/4D$ provided $C_c/C<<1$ and γ is nearly unity; the rate of drop of voltage is substantially equal to $2V_BD/(n+1)W^2$ after the voltage has dropped from near V_B to below 90% V_B where n is the exponent in $1/M=1-(V_c/V_B)^n$. If the ratio of C/C_c is too small, the collector voltage will not "bottom," i.e., drop to the base voltage; means of estimating the critical size of the capacitor are given. The analysis is based on an integral equation involving stored minority carrier charge in the base layer, which may be useful in other transient problems of transistors.

IT IS well known that a junction transistor biased into the range at which avalanche multiplication is important will discharge a capacitor connecting emitter and collector, and generate a wave of voltage which has high harmonic content. The analysis of this discharge wave poses difficult mathematical problems, although the physics of the problem, in principle at least, is relatively simple.

The transition results from feedback due to secondary carriers arriving back at the base, and provoking injection of minority carriers from the emitter. As a result, the collector current rises. It will be shown that this rise is initially exponential, with a time constant that depends on the collector voltage.

The exponential increase continues until the collector voltage drops appreciably. From this point on the problem becomes mathematically more difficult, because it is essentially nonlinear in the voltage and current variables.

The problem is treated in the large signal range by making use of the concept of the stored minority carrier charge in the base layer. This quantity, denoted by Q_s, initially increases exponentially but approaches a maximum value as the avalanche multiplication drops. The variation of Q_s with time can be analyzed with the aid of an integral equation which can be treated approximately.

The general conclusions reached are as follows:

1. During the initial constant voltage phase of the build-up, the collector current I_c and the stored charge Q_s build up exponentially as $\exp(\lambda t)$ where

$$\lambda=(D/W^2)(\ln 2M)^2$$

where D is the diffusion constant of minority

Paper 58-1249, recommended by the AIEE Semiconductor Metallic Rectifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted July 10, 1958; made available for printing September 9, 1958.

W. SHOCKLEY and J. GIBBONS are with the Shockley Semiconductor Laboratory, Mountain View, Calif.

The work reported in this paper was supported in part by a contract with the U. S. Signal Corps.

carriers in the base layer, W is the width of the base layer, and M is the avalanche multiplication factor for minority carriers entering the collector junction from the base. For $M=10$, the squared factor is 9, and for $M=100$, it is 28. Thus multiplication can greatly increase the rate of build-up of current.

2. The larger the load capacitor, the faster the drop in voltage across the capacitor. This result is at first surprising. It is derived assuming that a linear approximation may be used in treating minority carrier motion in the base layer but may be more generally valid. The external capacitor can be considered as large when it has many times the capacitance of the collector junction. If the load capacitor is not large compared to the collector-junction capacitance, the transistor may not be able to bottom, i.e., completely discharge the load capacitor with a sharp voltage wave.

3. The current into the load capacitor rises quite abruptly and reaches nearly its peak value before the capacitor is substantially discharged. The time required for the current to increase from 25% to 75% of its peak value is of the order of $W^2/4D$.

The results are based upon an especially simple process for turning on the transistor. As discussed in the following section, it is possible to consider a situation in which the transistor is biased by high-impedance current sources so that it is in a negative-resistance condition between emitter and collector terminals. If a capacitor, biased to the same voltage, is connected across these terminals, an unstable situation is produced such that an initial transient of increasing current will build up.

Important practical cases correspond to somewhat different initial conditions. For example, an effective varying alpha may result from connecting a resistor between base and emitter; then the transient may be initiated by increasing forward bias across the emitter junction. Alternatively, a voltage pulse may be applied to drive the collector momentarily into the breakdown range. Such cases will require treatments differing from that presented here, but many of the essential features will be the same.

The Constant-Voltage Case

In Fig. 1 the sign conventions used in this treatment are illustrated. The currents I_e, I_b, and I_c are the total currents flowing into the terminals of the *p-n-p* transistor. The current I is introduced to eliminate minus signs in the equations that follow.

Consider first the situation corresponding to the switch S being open. The resistor, supposed to be very large in value, charges the load capacitor C to the potential of the collector terminal. The battery of potential $-V_B$ is discussed in the next section. Closing the switch S changes the impedance across the emitter to collector terminals and leads to the transient build-up discussed in the following.

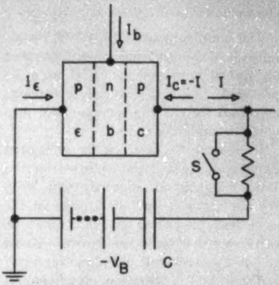

Fig. 1. Circuit for establishing initial conditions for small transients

First, several quantities concerned with holes will be defined:

γ = emitter efficiency = hole current injected across emitter junction divided by I_e

and the base-layer transmission factor β

$$I_{mc}=\beta\gamma I_e+I_{co}$$

where I_{mc} is the minority-carrier current reaching the collector junction from the base. In this treatment β is not simply a constant but an operator which operates upon a varying current γI_e to give I_{mc}. The appropriate form for β will be derived in the following. The current I_{co} is the minority current which would reach the collector junction for zero emitter current. Assume, for simplicity, that this current I_{co} all comes out of the base and neglect space-charge generation and electron current coming from the collector body.

The multiplication factor for holes at the collector junction is M so that

$$I=I_c=MI_{mc}$$

where M is a function of the voltage across the collector junction, V_c. Where it is necessary to use the functional form for M, use the approximation

$$M(|V_c|)=\left[1-\left(\frac{|V_c|}{V_B}\right)^n\right]^{-1}$$

where $|V_c|$ is the absolute value of collector voltage and V_B the absolute value of the breakdown voltage.

If a constant base current I_b flows, the current-voltage relationship between I and V_c may be obtained by noting that

$$I_e=I-I_b$$

so that

$$I=MI_{mc}=M[I_{co}+\alpha(I-I_b)]$$

where α is the conventional alpha for d-c conditions and in general is given by

$$\alpha=\beta_\gamma$$

Dividing I by MI leads to

$$\frac{1}{M}=\frac{I_{co}-\alpha I_b}{I}+\alpha$$

In order to visualize the behavior of this equation, consider cases in which

$$I\geq I_b>I_{co}$$

This corresponds to current in the reverse direction at the collector junction and a flow of majority carriers out of the base, i.e., the base current is trying to reverse bias the emitter junction. Now I is increased from I_b to higher values. If I is equal to I_b, the value of M is

$$\frac{1}{M}=\frac{I_{co}}{I_b}$$

thus, if $I_b=100I_{co}$, for example, M is 100. Now, suppose I is increased to $2I_1$, then M is given by

$$\frac{1}{M}=\frac{I_{co}}{2I_b}+\frac{\alpha}{2}$$

If I_b is equal to $100I_{co}$ and α is near unity, M is reduced to about 2. Thus, increasing I from I_b to $2I_b$ produces a large drop in collector voltage.

Algebraically this change in voltage corresponds to a negative resistance. Thus, in increasing I from I_b to $2I_b$, the change in I_c is $-I_b$ while the change in V_c is from a negative value near $-V_B$ to a much less negative value. Thus a negative change in I_c is produced by a positive change in V_c.

Now, suppose that the switch is closed when the bias currents are such that M is large and I some what greater than I_b. The same bias currents, I_b and I_c, are maintained from the current sources. Let the deviation of the emitter current be δI_e from its previous value. This produces a carrier current across the collector junction given by

$$M\beta\gamma\delta I_e$$

This added current cannot flow out through the bias supplies and acts to charge the two capacitors, namely C and the collector junction capacitance C_c.

Fig. 2 represents the equivalent circuit for the situation under discussion. The transient current δI_e flows around the circuit and produces a current source across the collector junction. (The expressions in parentheses on the figure are discussed in the following section.)

The transient build-up results from the fact that the current source acts to put charge on both C_c and C and that portion which charges C also flows in the emitter lead and enhances the current source. Since a fraction $C/(C+C_c)$ of the current source flows through C, then

$$\delta I_e = \delta I_e \beta\gamma MC/(C+C_c)$$
$$= \delta I_e \beta\gamma M_e$$

where

$$M_e = MC/(C+C_c)$$

is the effective multiplication factor by which unit current of minority carriers entering the collector junction is multiplied in producing current in the emitter lead.

If the bias is such that the device is in the negative-resistance region, then αI_b is greater than I_{co} and

$$\frac{1}{M\alpha} = 1 - \alpha \frac{I_e - I_{co}}{I}$$

so that $M\alpha$ is greater than unity for d-c or low-frequency changes. Evidently, if $M_e\beta\gamma$ is greater than unity, an increase in emitter current δI_e will produce a bigger increase in emitter current and build-up will occur.

The rate of build-up is limited by the delay for diffusion. If the emitter current builds up rapidly, the ratio of collector current to emitter current drops. This effect can be dealt with by considering β to be an appropriate function of the rate of build-up and choosing the rate so that the gain factor $M_e\beta\gamma$ becomes unity:

$$M_e\beta\,(\text{rate of build-up})\,\gamma = 1$$

This equation corresponds to an exponentially growing current. This may be seen as follows: Let δp be the disturbance in $p(x, t)$ in the base layer corresponding to the transient disturbance following the closing of the switch. Let $x=0$ be the collector plane, and $x=-W$ be the emitter plane. Consider

$$\delta p(x, t) = -\exp(\lambda t)\sinh ax$$

This satisfies the continuity equation in the base layer if

$$a^2 = (\lambda + \nu)/D$$

where ν is the reciprocal of the hole lifetime. Furthermore, δp is zero at the collector junction. The ratio of current at collector to current at emitter for δp is β, which is a function of λ, and is

$$\beta(\lambda) = 1/\cosh aW$$

If it is assumed that all the current carried across the emitter is due to injection (and not to space-charge recombination), γ will be independent of the magnitude of the current, but it may depend upon λ since as λ increases, the ratio of diffusion current to carrier density increases at the emitter junction. This dependence of γ upon λ will be neglected here; it may play a significant role in silicon devices, however.

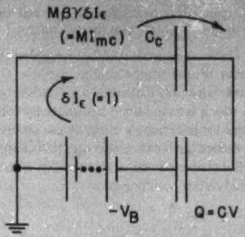

Fig. 2. Equivalent circuit for small and large transients

The equation in δI_e may thus be valid if the build-up constant λ satisfies

$$\beta(\lambda)\gamma M_e = 1$$

For values of γM_e larger than 3, the hyperbolic cosine in β may be represented by its first term and λ becomes

$$\lambda = [D(\ln 2\gamma M_e)^2/W^2] - \nu$$

This is the result quoted previously for the case of $C/C_c = \infty$ (so that M equals M_e) and unit emitter efficiency. The more general expression for $\gamma M_e < 2$ is

$$\lambda = (D/W^2)(\cosh^{-1}\gamma M_e)^2 - \nu$$

The Large-Disturbance Case and the Charge Variables

For the situations with which this paper is chiefly concerned, the current values are so large during the transient phase that the biasing currents are negligible in comparison. Accordingly, it will be assumed in this section that at the same instant that the switch S is closed, the circuit to the collector current source is opened. It will be assumed, initially, that I_b remains unchanged.

The advantage of assuming that the collector current source is reduced to zero is that this permits certain simple conclusions about the relationship between three quantities having the dimension of charge. The first of these quantities is simply the charge Q on the capacitor C of Figs. 1 and 2. First, consider the relationship of Q to Q_{mc} which is defined by

$$dQ_{mc}/dt = I_{mc}$$

Thus, Q_{mc} is, except for an additive constant, the total charge carried by minority carriers arriving from the base at the collector junction. There is a relatively simple relationship between Q_{mc} and Q which is independent of the initial conditions of the discharge and of its progress. To derive this relationship, the relationship between M and Q must be considered.

The battery of potential $-V_B$ has been chosen so that when $Q=0$, V_c is at the breakdown potential and when

$$Q = Q_B \equiv CV_B$$

the voltage across the collector junction is zero. These relationships correspond to neglecting the voltage drop across the emitter which is in any event small, and furthermore, nearly constant since the emitter junction is forward-biased during the transient that is being studied.

It is convenient to express M as a function of Q and to introduce an approximation valid near breakdown in terms of Q_n as follows:

$$\frac{1}{M} = 1 - \left(1 - \frac{Q}{Q_B}\right)^n$$
$$\doteq Q/Q_n \text{ for } Q < Q_n$$

$$Q_n = Q_B/n$$

The first equality involves writing $|V_c|/V_B$ in terms of Q for the expression of the preceding section.

Now consider what occurs when a charge

$$dQ = Idt = \delta I_e dt$$

flows around the circuit of Fig. 2; the equality of δI_e and δI results from disconnecting the current source to the collector. Evidently

$$dQ = \frac{C}{C+C_e} M(Q)dQ_{mc}$$

since the entrance of a charge dQ_{mc} into the space-charge region of the collector results in a charge $M(Q)$ times larger appearing on the two capacitors and a fraction $C/(C+C_c)$ of this appearing on the capacitor C. Thus the relationship

$$dQ_{mc} = dQ/M_e(Q)$$

results where again use the effective multiplication factor

$$M_e(Q) = CM(Q)/(C+C_c)$$

is used. It should be noted that C_c is also a function of Q and this should be thought as being included in $M_e(Q)$.

Thus, Q_{mc} can be expressed as a function of Q by integrating

$$Q_{mc} = \int_0^Q dQ/M_e(Q)$$

where the additive constant in Q_{mc} is chosen so that Q_{mc} and Q both vanish as breakdown is approached.

If the dependence of C_c upon Q is neglected and the analytical approximation for $M(Q)$ is used, then

$$Q_{mc}(Q) = \frac{C+C_c}{C}\left\{Q-\frac{Q_B}{n+1}\left[1-\left(1-\frac{Q}{Q_B}\right)^{n+1}\right]\right\}$$

For small values of Q/Q_B this reduces to

$$Q_{mc} \doteq \frac{(C+C_c)Q^2}{2CQ_n}$$

It is seen that Q_{mc} is less than Q for small values of Q and for $Q << Q_n$ the ratio of Q_{mc} to Q is very small. This means that when Q is small, $M(Q)$ is large, and a small change in Q_{mc} produces a big change in Q.

Since dQ is the charge flowing around the circuit of Fig. 2, it is evident that when Q is small, carriers are being injected into the base layer in amount γdQ to a greater extent that they are leaving at the collector in amount $dQ/M(Q)$. Thus, in effect injected carriers are being stored in the base layer.

If it is assumed that there is a constant emitter efficiency γ, a stored-charge variable Q_s can be introduced by the equation

$$Q_s \equiv \gamma Q - Q_{mc}$$

For the analytic approximation discussed in the foregoing:

$$Q_s = \left(\gamma - \frac{C+C_c}{C}\right)Q + \frac{(C+C_c)Q_B}{C(n+1)}\left[1-\left(1-\frac{Q}{Q_B}\right)^{n+1}\right]$$

For the simplified situation of $\gamma=1$ and $C << C$ this reduces to

$$Q_s = \frac{Q_B}{n+1}[1-u^{n+1}]$$

where

$$u \equiv |V_c|/V_B = 1-(Q/Q_B)$$

The actual charge of minority carriers present in the base layer will not vary directly as Q_s because minority carriers may be lost by recombination within the base layer as well as by emerging as dQ_{mc}. Furthermore, the current I_b of Fig. 1 must be subtracted from the current I flowing into C in order to obtain I_e. During the important part of the transient, the current I_B will be small compared to I and can usually be neglected.

Two important problems can now be considered:

1. What, approximately, is the maximum rate of voltage drop that can be produced by the transient?
2. How does the maximum rate and the amount of voltage drop depend upon C?

These questions can be answered in terms of the stored-charge variable Q_s. First, note that if there is a stored charge Q_s which is maintained substantially constant by injecting as much at the emitter as comes out at the collector, this charge will distribute itself in the base layer in a steady-state configuration with

$$p(x) = -p_0 x/W$$

where P_0 is the density at $x=-W$ the emitter junction. The values of Q_s and I_{mc} corresponding to this are

$$Q_s = qP_0W/2$$

$$I_{mc} = qP_0D/W$$

and the ratio of these two quantities, denoted by ν_s

$$\nu_s = I_{mc}/Q_s = \frac{2D}{W^2}$$

is in effect the number of times per unit time the charge Q_s must be replenished by injection to make up for the loss due to I_{mc} in order to keep Q_s constant.

As will be discussed in a subsequent section, if a charge Q_s is injected and maintained, then the current I_{mc} is somewhat delayed after the injection, in fact by a time approximately equal to $1/6\nu_s$, before it builds up to a maximum of $\nu_s Q_s$.

The maximum rate of voltage drop on the capacitor C will be $M_e I_{mc}/C$. Inspection of the analytic expression for Q_s shows that I_{mc}/C will be increased by increasing γ and by decreasing C_c/C. The optimum case corresponds to the maximum value for Q_s/C which leads to a maximum rate of drop as V_c approaches zero and M approaches unity of

$$dV/dt = \nu_s Q_s/C = \nu_s V/(n+1)$$

As will be discussed in the following, a slightly higher rate of fall may occur early in the discharge waveform while multiplication is still occurring.

Decreasing C compared to C_c leads to increasing Q_{mc} in respect to Q_B and to decreased values of Q_s/C. Thus increasing C increases dV/dt as was pointed out previously.

If γ is small or if C/C_c is not large enough, the voltage across the collector junction may not fall to zero. This conclusion may be reached by considering the expression for dQ_s:

$$dQ_s = \left[\gamma - \frac{C+C_c}{CM(Q)}\right]dQ$$

Unless $\gamma=1$ and $C_c/C=0$, this expression will become negative as Q approaches Q_B and M approaches unity. Negative values mean that there is a net loss of minority carriers stored in the base. If γ is small enough and C_c/C large enough, not only will dQ_s become negative, but Q_s will become zero before Q reaches Q_B. This situation means that minority carriers stored while M was large, get used up until finally none are left in the base and I_{mc} becomes zero.

Thus the extent of the downward excursion may be estimated by finding the value of Q for which $Q_s=0$.

Two refinements shoud be mentioned. The initial transient may start at some voltage corresponding to Q_o and Q_{so}. In this case, the excursion will build up exponentially, as discussed in the previous section, with $M_e(Q_o)$ applying in evaluating λ. It can then proceed only so far that Q_s returns to Q_{so}. Furthermore, if ν, the reciprocal of minority carrier lifetime, is not much less than λ, the excursion will stop sooner.

However, if the collector current generator of Fig. 1 is disconnected, V_c will eventually drop to zero due to the I_{co} term. This represents a very slow drop compared to the rate $\nu_s V_B/(n+1)$ considered in this section.

The next sections will consider the transition from the initial exponential rate of the preceding section to the final rate estimated in this section.

The S(t) Formulation

In this section the discharge-of-the-capacitor problem will be formulated in terms of an integral equation for dQ_s/dt. The final result will involve expressing I_{mc} in terms of dQ_s/dt. Once this has been done the equation for dQ_s/dt is obtained by writing

$$dQ_s/dt = [\gamma M_e(Q_s) - 1]I_{mc}$$

where the first term on the right represents the carrier injection into the base due to I_{mc} entering the space-charge layer and producing current around the circuit and the second term represents loss from the base.

In order to express I_{mc} in terms of Q_s, the function $S(t)$ is introduced. This function is defined in terms of the properties of the base layer and may include drift-transistor effects. $S(t)$ is defined as follows: At $t=0$ inject unit charge across the emitter junction. Thereafter, maintain the boundary condition $p=0$ at the collector. Inject across the emitter a current exactly equal to the collector current I_{mc}. It is evident that $S(t)$ corresponds to a situation in which Q_s increases by unity at $t=0$ and thereafter remains constant.

If Q_s is known as a function of t, then I_{me} can be obtained by considering $Q_s(t)$ to have resulted from a set of step functions at earlier times, denoted by s, such that each step is

$$\dot{Q}_s(s)ds$$

Each such step produces a current at time t which is $S(t-s)$ times this step. Hence

$$I_{me}(t)=\int_{-\infty}^{t} S(t-s)\dot{Q}_s(s)ds$$

This leads to

$$\dot{Q}_s(t)=[\gamma M(Q_s)-1]\int_{-\infty}^{t} S(t-s)\dot{Q}_s(s)ds$$

which will be used as a basis of analyzing the transient behavior for large signals.

If the lifetime is uniform in the base layer with reciprocal lifetime ν, $S(t)$ may be expressed as a product

$$S(t)=\exp(-\nu t)S_o(t)$$

The function $S_o(t)$ corresponds to finding a solution for minority carriers in the base layer satisfying

$$\partial p/\partial t=D\frac{\partial^2 p}{\partial x^2}-\frac{\partial}{\partial x}(\mu pE)$$

where D and μ are minority-carrier diffusion constant and mobility and E is the electric field. The density p must satisfy the boundary conditions

$p=0$ at $x=0$, the collector

and

$$S(t)=q\left(-D\frac{\partial p}{\partial x}+\mu pE\right)_{-W}=q\left(-D\frac{\partial p}{\partial x}+\mu pE\right)_0$$

which states that the collector and emitter currents are equal and equal to $S(t)$. At $t=0$, p must vanish except at $x=-W$ and the integral there must give unit charge for qp.

If $S_o(t)$ and its corresponding $p_o(x, t)$ satisfy these conditions, then it follows that $S(t)$ and $\exp(-\nu t)p_o(x, t)$ satisfy the boundary and initial conditions and also the continuity equation with recombination included.

In the next section, it will be shown how $S_o(t)$ may be calculated for a uniform base layer with no electric field. If a field is present, $S_o(t)$ may have a complicated behavior and may be represented as a series of pulses for short times. For long times $S_o(t)$ may be calculated from a steady state $p_o(x, \infty)$ and its value is then simply

$$S_o(\infty)=\text{current due to } p_o(x, \infty)/\text{charge due to } p_o(x, \infty)$$

For the uniform base layer its value is ν_s, given in the preceding section,

$$\nu_s=2D/W^2$$

The value for a uniform field is given in the next section.

Next, a quantity derived from $S_o(t)$ and its limiting value ν_s will be introduced by the expression

$$\int_0^{\infty}[\nu_s-S_o(t)]dt=f=\nu_s t_s$$

This quantity has no dimensions. It indicates by what amount $S_o(t)$ falls short of reaching its final value ν_s at $t=0$. The integrand vanishes for large t and in effect $S_o(t)$ is negligible for an average time t_s, defined by the foregoing equation, and thereafter $S_o(t)$ equals ν_s.

If Q_s increases at a substantially constant rate for a time large compared to t_s, then $\dot{Q}_s$ may be taken out of the integral for I_{me} by the following steps:

$$\begin{aligned}I_{me}(t)&=\int_{-\infty}^{t}[S_o(t-s)-\nu_s]\dot{Q}_s(s)ds+\nu_s\int_{-\infty}^{t}\dot{Q}_s(s)ds\\&=\dot{Q}_s(t)\int_{-\infty}^{0}[S_o(-r)-\nu_s]dr+\nu_s[Q_s(t)-Q(-\infty)]\\&=\nu_s[Q_s(t)-Q_{s0}]-f\dot{Q}(t)\end{aligned}$$

Thus the current I_{me} is the current due to the added stored charge during the transient except for the charge added during the interval $t-t_s$ to t which would contribute

$$\nu_s t_s\dot{Q}_s(t)=f\dot{Q}_s$$

if $S_o(t)$ rose to its final value ν_s infinitely fast.

This approximation is very inaccurate during the early exponential phase of the first section of this paper. However, as discussed in the second section, Q_s approaches a limiting value and thus $\dot{Q}_s$ must have a maximum. Near the maximum $\dot{Q}_s$ is approximately constant and near that time I_{me} may be estimated fairly accurately from the approximate expression derived in the foregoing.

If the transient starts with a relatively high value of M and nearly negligible value of Q_{s0}, then near the maximum value of $\dot{Q}_s$ one may write

$$\dot{Q}_s=[\gamma M_s(Q_s)-1](\nu_s Q_s-f\dot{Q}_s)$$

This equation may be solved for $\dot{Q}_s$ and from this the following expressions can be obtained

$$\dot{Q}_s=\frac{[\gamma M_s(Q_s)-1]\nu_s Q_s}{1-f+f\gamma M_s(Q_s)}$$

$$\dot{Q}-I=\frac{M_s(Q_s)\nu_s Q_s}{1-f+f\gamma M_s(Q_s)}$$

These expressions will be used later in estimating the characteritistics of the transient behavior.

The Form of S(t)

For a uniform base layer with collector junction at $x=0$ and emitter at $x=-W$, a method of images can be employed to find $p_o(x, t)$ corresponding to $S_o(t)$. If $U(x_o, x, t)=U(x_o)$ denotes a delta function of holes located at $x=x_o$ at $t=0$, which subsequently spreads into the normal gaussian distribution, then

$$p_o(x, t)=2\sum_n nU(-nW)$$

The fact that this gives the same current across all planes of the form $x=nW$ may be verified by adding to $p_o(x, t)$ the series

$$\sum_n U(nW)$$

which shifts $p_o(x, t)$ by W to the right without changing the currents on the $x=nW$ planes.

The gaussian distributions of $p_o(x, t)$ when spread out produce an average density which finally varies as

$$p_o(x, \infty)=-2x/W^2$$

and correctly gives unit numbers of holes between $x=-W$ and $x=0$.

Numerical calculations of $S_o(t)$, which can readily be done by differentiating term by term of the gaussian series, show that the rise of $S_o(t)$ occurs with an average delay of about $1/6\nu_s$ so that the quantity f of the preceding section is about 1/6.

If a strong drift field exists in the base layer, the problem becomes more complicated. The final value ν_s can, however, be evaluated by considering the steady state and is found to be

$$\nu_s(E)=(D/W^2)y^2/(y+e^{-y}-1)$$

where

$$y=qEW/kT$$

is the number of units of thermal voltage across the base layer.

$S_o(t)$ and $S(t)$ are related to somewhat simpler functions $B_o(t)$ and $B(t)$. The B's are the currents which would flow subsequent to unit injection across the emitter followed by zero emitter current thereafter. If S_o^0, S^0, B_o^0, and B^0 denote the operations corresponding to obtaining I_{me} from $\dot{Q}_s$ in the preceding section, then it follows that

Table I. Approach to Maximum Current

M	10	6.70	5	3.30	2.5	2	1.70	1.40
u^3	0.90	0.85	0.80	0.70	0.6	0.50	0.40	0.30
$F(u)$	0.48	0.58	0.64	0.64	0.6	0.54	0.42	0.32
$G(u)$	0.53	0.69	0.79	0.90	1.0	1.04	1.06	1.06

$$S_e^0=B^0_e+(B_e^0)^2+(B_e^0)^3+\dots$$

and

$$S^0=B^0+(B^0)^2+(B^0)^3+\dots$$

In effect each term represents the delayed effect of feeding the current of the previous term back into the emitter.

$B_e(t)$ can be represented by a series of gaussian functions of alternating signs on all planes of the form $x=(2n+1)W$. The corresponding hole density can be expanded in a series of the form $\sin (2n+1)\pi x/2W$. A series of the form $x \cos 2\pi nx/W$ is required at $t=0$ for $S_e(t)$.

Estimate of the Approach to Maximum Current

The result needed from the last section in order to treat the equations of the section on "The $S(t)$ Formulation" was the value of f, which is approximately 1/6.

If it is now assumed the the transient takes place in a time small compared to carrier lifetimes, so that $S_e(t)$ can be used in place of S, and Q_{so} is taken as near zero and $\gamma=1$ and $C_e/C=0$, then the afore-mentioned equations become

$$\dot{Q}_s=[\nu_s Q_B/(n+1)]F(u)$$

$$\dot{Q}=[\nu_s Q_B/(n+1)]G(u)$$

$$F(u)=u^n G(u)$$

$$G(u)=(1-u^{n+1})/[1-(1-f)u^n]$$

$$u\equiv|V_c|/V_B=1-(Q/Q_B)$$

For the typical value of 3 for n the following values are obtained for $F(u)$, $G(u)$, and $M(u)$ where

$$M(u)=[1-u^n]^{-1}$$

For $u=0$, corresponding to zero collector voltage, $M(u)$ and $G(u)$ are unity and $F(u)$ is zero.

Table I shows that $\dot{Q}_s$, or $F(u)$, has a maximum for M about 4. $G(u)$ is seen to exceed unity slightly showing that dV/dt is slightly larger than its final value when M is about 1.4, corresponding to $u=0.66$ or to a drop in voltage of about 1/3 from V_B.

The time required for the current to build up from $G(u)=0.5$ to $G(u)=0.9$ can be estimated as follows: The corresponding values of u are 0.97 and 0.89 corresponding to a change of charge 0.08 Q_B. The average value of $G(u)$ is 0.7. Hence the time is

$$t=0.08Q_B/[\nu_s Q_B\,0.7/(n+1)]$$
$$=0.44/\nu_s=0.22W^2/D$$

It is probable that this estimate is somewhat long for the following reason:

When the current is building up rapidly the correction term obtained by taking $\dot{Q}_s$ out of the integral in the section, "The $S(t)$ Formulation," overestimates the correction. This will lead to slightly larger values for $\dot{Q}_s$ and Q for values of M as large as 10. For $M=10$, the λ constant of the first section is given by

$$1/\lambda=0.11W^2/D$$

corresponding to an increase of a factor of $e=2.73$ in about $(1/9)W^2/D$.

From this it is concluded that the current will increase exponentially to about half its maximum value with an exponential rate of rise of greater than $10D/W^2$ at $M=10$ or about 3% below V_B. In a subsequent time of about $0.2W^2/D$ the voltage will drop to about 11% below V_B and the current to the load will be about 85% of its final value. Peak current will occur at about 33% V_B and substantially constant current will then flow until the collector voltage drops to zero.

Optimal Utilization and Extension of Interoffice Trunking Facilities

R. E. KALABA
NONMEMBER AIEE

M. L. JUNCOSA
NONMEMBER AIEE

MANY optimization problems in the communications field are characterized by the fact that they involve large numbers of highly interconnected variables. This has forced communications engineers, planners, and managers to resort to various suboptimization schemes, many of which have been of the empirical or trial-and-error types. This situation has in large part been caused by the lack of adequate mathematical and numerical techniques for analyzing and solving such problems.

The rapid development during the past decade of large-scale high-speed digital computing machines and the concurrent growth of the new mathematical tool, linear programming[1,2] has made many multivariable problems, heretofore thought unmanageable, numerically solvable. In an earlier paper[3] the authors gave a general introduction to the potential role of linear programming in the communications field. Here, for the purpose of illustrating its applicability, they show how to handle several interoffice trunking problems of general nature and interest relating to the optimal utilization of existing plant as well as to the minimal cost design of additional facilities. That linear programming formulations are particularly well-suited to these classes of problems is made evident by the fact that additional features such as growth of a system over a period of years, restrictions on equipment availability, etc., are readily incorporated into the models. Several extensions of the basic model will be given to illustrate this point. Thus the inherent flexibility of the models is readily made apparent.

The Model

The system to be considered consists of a set of n points, the stations or central offices, between which pass a set of links. These links are assumed to be bidirectional; e.g., they can be used for communication in either direction. They

Paper 58-1245, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted February 28, 1958; made available for printing September 9, 1958.

R. E. KALABA and M. L. JUNCOSA are with The Rand Corporation, Santa Monica, Calif.

The authors are indebted to R. P. Thompson and S. E. Mikkelsen of the Pacific Telephone and Telegraph Company for bringing this class of problems to their attention and for their interest and encouragement.

could have just as easily been assumed unidirectional links as, for example, in the case of radio links. At each station jumper connections or patches between links are made so that through trunk lines between near or distant stations may be synthesized from links connected in series. It is assumed further that, as a consequence of traffic studies and otherwise, the desired numbers of trunks between all pairs of stations in the network are known.

With this model the problems to be treated here fall into the following two general classes:

1. Given a network of existing links among the n stations and a set of demands for interoffice trunks, how should these links be connected so the maximal possible number of desired interoffice trunks is realized?
2. Given, in addition to the foregoing, a set of unit costs for constructing additional links, how should the existing plant be extended so that increased demands for trunks may be met at minimal cost? This request, of course, is not only for decisions as to what links are to be added, but for decisions as to how all of the links are to be connected together in the extended system.

In many practical problems, especially for larger systems, one may encounter restrictions on the types as well as on the numbers of links that can be patched together in a single trunk without adding any more signal-enhancing equipment than is already in the circuits. For simplicity and to illustrate the methodology, the next section will consider unrestricted systems, i.e., systems for which it is assumed that any set of links joined together in series will provide a satisfactory trunk. The inclusion of restrictions not considered there complicates the problems conceptually and adds greatly to the amount of numerical computation necessary for solution. In a later section the handling of certain types of these restricted systems will be considered.

Unrestricted Systems

Using the afore-mentioned model, first consider a problem of class 1, i.e., of optimal plant utilization. Later problems of class 2, i.e., of minimal cost plant extension, will be considered.

OPTIMAL PLANT UTILIZATION

Let

a_{ij} = known desired number of trunks running between station i and station j to satisfy the needs of station i to communicate with station j

c_{ij} = known number of existing links between stations i and j available for use in trunks running in either direction

x_{ijk} = unknown number of links running directly between i and j which are connected at j to links ultimately to terminate at k

The range of the indexes i, j, and k is the integers 1, 2, . . ., n. Since the links are bidirectional, redundance in the conditions is eliminated by requiring that i be less than j in the definition of c_{ij}. Furthermore, in the definitions x_{ijk} assume $i \neq j$, $i \neq k$ for obvious reasons. Since x_{ijj} is the number of trunks to terminate at j having a link between i and j as their terminal leg, it is clear that one seeks to maximize the total number of completed desired trunks or equivalently the total number of desired terminal links, namely, the quantity

$$\sum_{\substack{i,j \\ i \neq j}} x_{ijj}$$

subject to a number of linear restrictions on the unknown variables x_{ijk}.

First of all, the x_{ijk} are to be nonnegative. Second, the total number of trunks in either direction using the links running between stations i and j cannot exceed the total number of existing links c_{ij} between stations i and j. Last, the total number of trunks emerging from the station i ultimately to be terminated at station j must not exceed the sum of the demand for trunks from station i to station j and the number of trunks entering station i ultimately to be terminated at station j. Consequently, the difference between the total number of trunks passing through station i on their way ultimately to terminate at station j and the total number of trunks originating at station i ultimately to terminate at station j is not to exceed the total number of desired trunks running between stations i and j to satisfy the trunking requirement from station i to station j. It can be shown that this represents a complete accounting of all the restraints on x_{ijk} appearing in the problem.

This leads to the following mathematical problem:

Maximize

$$\sum_{i,j} x_{ijj} \tag{1}$$

subject to the conditions

$$x_{ijk} \geq 0 \tag{2}$$

$$\sum_k x_{jik} + \sum_k x_{ijk} \leq c_{ij}, \quad i<j \tag{3}$$

$$\sum_k x_{ikj} - \sum_k x_{kij} \leq a_{ij}, \quad i \neq j \tag{4}$$

This is a linear programming problem and may be treated by the general techniques available for handling such problems; in particular, the general simplex method of George Dantzig[4] is available for the numerical computation of answers. Problems of the sort considered in this section involving up to a dozen or so stations in the network can be handled by the simplex method using such codes as those developed by W. Orchard-Hays for the IBM (International Business Machines Corporation) *704* machine. It is clear that special computational algorithms for this and related problems will have to be developed if great strides forward in increasing both the speeds of solutions and the size of the networks handled are to be realized. The authors are investigating a specialization of the simplex method for these problems based on the observation that the matrices of coefficients in the system of inequalities 3 and 4 are very sparse, having only $n(n-1) \times (3n-4)$ nonzero elements out of a total of $(3/2)n^2(n-1)^2$ elements, and that these nonzero elements are either $+1$ or -1. Another possibility is to attempt solution from several new points of view; see Bellman,[5,6] Boldyreff,[7] and Ford and Fulkerson.[8]

It frequently happens in practice that linear programming problems do not possess unique solutions, i.e., different sets of values of the variables may yield the same optimal value of the objective function. This is usually the case here. Consequently, it is desirable to add a secondary constraint to the problem that the optimal value of equation 1 is to be attained using a minimal number of the existing links. At present this can be accomplished in two stages, by first solving the original problem stated and then solving a similar problem wherein the restraints, equations 2, 3, and 4, are retained and supplemented by the one additional restraint that the linear form in equation 1 take on the value obtained in the solution of the first stage, and the objective is to minimize

$$\sum_{i,j,k} x_{ijk} \tag{5}$$

The solution of this problem provides that after having satisfied as many of the original demands for trunks as possible a maximal number of spare links will be available for some additional trunks to handle fluctuations in demand, uncertain traffic estimates, etc.

An alternative procedure to obtain an optimal spare solution is to maximize

$$\sum_{i,j} x_{ijj} - \epsilon \sum_{i,j,k} x_{ijk} \tag{6}$$

subject to the condition, equations 2, 3, and 4 of the first problems, and ϵ is a positive fraction. Solutions of this problem will guarantee a number of completed trunks that will exceed the fraction 1-ϵ of the maximum number of trunks that can possibly be computed with a solution of the first problem, and it will do so with a maximum of spares left over. Thus choosing ϵ to be, say, 0.01, the solution of this problem gives at least 99% of the maximum possible number of completable trunks with maximum efficiency. This is not an unreasonable policy to follow since it is doubtful that the dispersion of estimates of the a_{ij} is as low as 1%. Permitting this slight tolerance in achieving the goal of maximum possible satisfaction of the demands for trunks reduces the computation to the solution of one problem instead of two.

A final and very important step in the mechanization of this work is to program the computer to print out exactly what connections are to be made at each station. Thus the process can be made automatic from the determination of the a_{ij} and c_{ij} to the printing out of trunk facility orders to the technicians regarding the connections to be made at each station.

NUMERICAL EXAMPLE

Using the linear programming point of view, numerical experiments have been set up and carried out on several interoffice trunking problems using the Johnniac, one of the Rand Corporation's large-scale high-speed computing machines. A representative example which was considered is the following 7-station optimal utilization problem.

The set of users' demands is given by the matrix

$$(a_{ij})=\begin{bmatrix} 0 & 91 & 19 & 37 & 54 & 62 & 47\\ 38 & 0 & 50 & 5 & 86 & 72 & 39\\ 18 & 12 & 0 & 78 & 43 & 52 & 110\\ 63 & 22 & 9 & 0 & 88 & 16 & 22\\ 25 & 50 & 14 & 69 & 0 & 31 & 75\\ 57 & 84 & 61 & 48 & 53 & 0 & 83\\ 46 & 81 & 71 & 78 & 95 & 30 & 0 \end{bmatrix} \tag{7}$$

The set of available links is given by the matrix

$$(c_{ij})=\begin{bmatrix} 0 & 20 & 200 & 170 & 190 & 15 & 160\\ & & 180 & 180 & 40 & 50 & 65\\ & & & 210 & 175 & 140 & 20\\ & & & & 75 & 180 & 140\\ & & & & & 170 & 30\\ & & & & & & 140\\ 0 & & & & & & 0 \end{bmatrix} \tag{8}$$

The solution is that it is possible to complete 1,921 trunks, a result which may be obtained by hand computation. It is not a simple matter however, to obtain a most efficient or "maximal spare" solution, that is, one for which as many spares as possible remain, especially in such a problem, where the capacities have been chosen so out of keeping with the demands. The result is that the maximal of spares is 11. A set $\{x_{ijk}\}$ providing this solution is

$x_{122}=6$ $x_{225}=49$ $x_{377}=20$ $x_{633}=86$
$x_{123}=45$ $x_{244}=5$ $x_{411}=63$ $x_{643}=84$
$x_{133}=65$ $x_{246}=15$ $x_{415}=13$ $x_{644}=48$
$x_{136}=2$ $x_{256}=23$ $x_{422}=160$ $x_{661}=57$
$x_{142}=40$ $x_{266}=50$ $x_{433}=9$ $x_{656}=55$
$x_{144}=37$ $x_{277}=39$ $x_{455}=75$ $x_{677}=83$
$x_{146}=17$ $x_{311}=56$ $x_{466}=48$ $x_{711}=46$
$x_{155}=81$ $x_{317}=21$ $x_{477}=62$ $x_{713}=46$
$x_{156}=27$ $x_{322}=43$ $x_{511}=82$ $x_{722}=26$
$x_{166}=15$ $x_{342}=14$ $x_{522}=17$ $x_{744}=78$
$x_{177}=68$ $x_{344}=147$ $x_{533}=14$ $x_{766}=25$
$x_{215}=14$ $x_{347}=40$ $x_{534}=69$ $x_{765}=2$
$x_{231}=38$ $x_{355}=92$ $x_{546}=58$ $x_{766}=30$
$x_{233}=50$ $x_{366}=54$ $x_{577}=30$

with all other x_{ijk} equal to zero.

Since this was a pilot attempt, no effort was made to streamline the computations on the Johnniac, but experience gained here indicated that machines such as the IBM *704* could handle problems of this size in a matter of minutes.

OPTIMAL PLANT EXTENSION

Now consider a simple optimal plant extension problem. It will be clear from the following and an earlier paper[3] how generalizations to random and multistage problems are made.

It is desired to augment the existing interoffice trunking facilities in such a manner so as to guarantee that a desired fraction ρ of the required trunks for the coming year will be available. After making estimates of the unit costs for putting in new links between all stations, show how to make the extension at minimum cost.

The notation introduced in a previous section is used with the modification that c_{ij}^* is the number of links between stations i and j in the existing plant and that c_{ij} is the number of links between stations i and j in the new extended plant, which is now an unknown variable to be determined in the solution of the problem. In addition, the generalized annual unit cost of adding links from i to j is denoted by d_{ij}. The problem then takes the form:

Minimize the cost

$$K=\sum_{i,j} d_{ij}(c_{ij}-c_{ij}^*) \tag{9}$$

subject to the constraints

$$x_{ijk}\geq 0,\quad c_{ij}\geq c_{ij}^* \tag{10}$$

$$\sum_k x_{ikj}-\sum_k x_{kij}\leq a_{ij} \tag{11}$$

$$\sum_k x_{jik}+\sum_k x_{ijk}\leq c_{ij},\ i<j \tag{12}$$

$$\sum_{i,j} x_{ijj}\Big/\sum_{i,j} a_{ij}\geq \rho \tag{13}$$

where ρ is the completion factor, i.e., the fraction of desired trunks completed.

This is once again a linear programming problem, and the same general remarks made in the foregoing apply. It should be pointed out here, though, that with the same code parameter studies may easily be carried out. In particular, the dependence of K, the cost of the augmentation, on ρ, the fraction of the desired trunks completed, may be obtained. This is most useful for planning purposes, since there may be some flexibility in the allocation of funds for the contemplated expansion; a curve of K as a function of ρ shows the least possible expenditure to achieve various fractions of desired trunks completed.

CONTINUATION OF NUMERICAL EXAMPLE

Now, reconsider the numerical example which has been given. It was pointed out that for the data given, only 1,921 trunks out of 2,184 desired could be completed using existing facilities. If the unit costs of adding additional links are given by the matrix

$$(d_{ij})=\begin{bmatrix} 0 & 100 & 200 & 100 & 141 & 223 & 200\\ 100 & 0 & 100 & 141 & 100 & 141 & 223\\ 200 & 100 & 0 & 223 & 141 & 100 & 282\\ 100 & 141 & 223 & 0 & 100 & 200 & 100\\ 141 & 100 & 141 & 100 & 0 & 100 & 141\\ 223 & 141 & 100 & 200 & 100 & 0 & 223\\ 200 & 223 & 282 & 100 & 141 & 223 & 0 \end{bmatrix} \tag{14}$$

what is the minimal cost at which links may be added so that all desired trunks may be obtained? In this case the minimal cost turns out to be 36,702.

Several other points were computed, and Fig. 1 is a plot of K versus ρ, the fraction of the desired channels completed. The additional points computed for the curve in Fig. 1 are (0.94, 17,051), (0.96, 23,210), and (0.98, 29,573). As can be

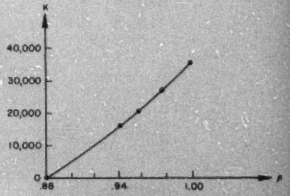

Fig. 1. Minimum cost as a function of completion ratio

seen, the curve is very nearly linear with a slight increase in slope as ρ nears one.

The curve of Fig. 1 gives the ideal minimum cost for which various values of the completion ratio may be obtained, and as such provides a goal which one might try to attain. In practice, due to restrictions not considered here, one would probably have to expend more than K to achieve ρ, so that actually attainable points lie above the curve shown.

EXTENSION WITH RANDOM DEMAND

The problem of designing an interoffice trunk system to accommodate a random future demand is more complicated than the above. A simple approach is to choose the expected values of the demands a_{ij} and use them exactly as one would known demands in the foregoing treatment of these problems. When the demands become known in the future the jumper corrections to be used in the implemented system can be recalculated as the solution of an appropriate optimal utilization problem. This, of course, is based on the assumption that the expected values will not be too far from the demands that actually develop.

The afore-mentioned treatment of the unknown demand situation does not use all the information available, for in general, one may be expected to make reasonable estimates of the actual probability distributions of the demands and not simply their expected values. At the expense of additional computation, one may consider these problems by introducing quantities $p^{(m)}(m=1, 2, \ldots, M)$, the respective probabilities that the matrices of demands $(a_{ij}^{(m)})$ will actually materialize. In addition, one lets the connections $x_{ijk}^{(m)}$ be made if demands $a_{ij}^{(m)}$ materialize. Though other criteria are possible, one might seek the minimal cost extensions to be made so that the expected value of the completion factor ρ will be equal or greater than a smallest acceptable ρ_0.[8] Mathematically the problem becomes that of minimizing

$$\sum_{i,j} d_{ij}(c_{ij}-c_{ij}^*) \tag{15}$$

subject to the conditions

$$x_{ijk}^{(m)} \geq 0,\ c_{ij} \geq c_{ij}^* \tag{16}$$

$$\sum_k x_{ijk}^{(m)} + \sum_k x_{jik}^{(m)} \leq c_{ij} \tag{17}$$

$$\sum_k x_{ikj}^{(m)} - \sum_k x_{kij}^{(m)} \leq a_{ij}^{(m)} \tag{18}$$

$$\sum_m p^{(m)}\Big(\sum_{i,j} x_{ijj}^{(m)} \Big/ \sum_{i,j} a_{ij}^{(m)}\Big) \geq \rho_0 \tag{19}$$

In still further considerations one may desire to plan for the optimal growth of the system over a period of years. Indication of how a multistage process of this sort may be handled are contained in an earlier paper.[8]

Restricted Systems

It is, of course, well-recognized that in many instances links may not be joined together arbitrarily to provide satisfactory service. For telephone plant, for example, such factors as length of the trunks, diameter of the wire, spacing between loading coils, and properties of the repeaters used all enter into a determination of whether or not a trunk composed of various links will be satisfactory. In addition, various equipment incompatibilities may be present. Methods of incorporating these features into the problem will now be considered.

Consider an optimal utilization problem in which various restrictions on the usability of trunks have been laid down. In the general case it now becomes necessary to introduce variables into the problem which are much more complex than the x_{ijk} of the unrestricted problem. In fact, one must now consider all ways of constructing a trunk from i to j and accept or reject them one by one.

Put

$x_{iab\ldots cj}^{\alpha\beta\ldots\gamma}$ = the number of trunks to be used connecting i and j and such that i is joined to a by a link of type α, a is joined to b by a link of type β, $\ldots$, and finally c is joined to j by a link of type γ (20)

If the resulting trunk is satisfactory, admit the corresponding variable into the problem; otherwise simply set it equal to zero. The mathematical problem is to maximize

$$\sum_{\left\{\substack{\text{all satis-}\\ \text{factory}\\ \text{trunks}}\right\}} x_{iab\ldots cj}^{\alpha\beta\ldots\gamma} \tag{21}$$

subject to the conditions

$$\sum_{\left\{\substack{\text{all trunks}\\ \text{joining}\\ i \text{ to } j}\right\}} x_{iab\ldots cj}^{\alpha\beta\ldots\gamma} \leq a_{ij} \tag{22}$$

and

$$\sum_{\left\{\substack{\text{all trunks}\\ \text{including a}\\ \text{link of type}\\ \beta \text{ between}\\ a \text{ and } b}\right\}} x_{iab\ldots cj}^{\alpha\beta\ldots\gamma} \leq c_{ab}^{\beta} \tag{23}$$

where c_{ab}^{β} is the number of available trunks from a to b of type β.

Though this is in general a formidable problem to deal with at present, in cases great simplification is possible; for example, if all trunks consisting of three or more links are considered unsatisfactory, and only one grade of transmission facility is available, one once again has to deal with relatively simple 3-subscript variables. Such problems involving a half-dozen stations and two types of links are within the capabilities of present-day electronic computers using nonspecialized codes.

Other methods are discussed in reference 9.

A number of other considerations, when expressed mathematically, appear in the form of linear equalities or inequalities, or they may be approximated by such expressions. For example, if transmission equipment is in short supply, one may append the condition in the optimal extension problem

$$\sum_{\substack{i,j\\ i\neq j}} (c_{ij}-c_{ij}^*) \leq C \tag{24}$$

where C is the total quantity of such equipment available during the period of plant extension. Various other features which may be incorporated are known and will be reported on in subsequent papers. A very frequent occurrence in the applications of linear programming has been that, as new considerations appear in problems, by the simple addition of more restraints it becomes possible to treat the new problems.

Conclusions

It has been shown that a number of interoffice trunking problems involving both usage and extension can be treated in a straightforward and computationally feasible manner by linear programming methods. To test feasibility two simple representative problems of types A and B were devised for a 7-station unrestricted system as indicated in an earlier section. The rapid, successful solution of these problems on one of Rand Corporation's computers, the Johnniac, as well as the extreme flexibility of the models introduced in this paper, indicates that, as the communications industry turns more and more to large-scale high-speed computers to cope with its large-scale systems problems, linear programming methods will become of increasing importance in carrying out these system-level optimizations.

◆

Discussion

George B. Dantzig (The Rand Corporation, Santa Monica, Calif.): Planners in the communication (and by analogy transport) industries are presented with a challenging new tool for interconnecting and extending units of their system, in an optimal manner. The authors demonstrate that a mathematical model, called the linear programming model, can be formulated that considers simultaneously: (1) the required service between points of the network, (2) the available in-place equipment, and (3) the cost of installing new equipment. Moreover they solved a rather complex example on an electronic computer to demonstrate that models formulated in this manner can be numerically solved.

Experience in other industries, particularly petroleum, indicates that the successful exploitation of this approach requires patience and willingness to begin with models, modest in scope and detail, and eventually to expand the model to reap its full potential.

The communications industry has a rich heritage of planning tools. Hence any new method to compete must overcome the "handicap" of entrenched procedures not present in other industries. However, considering the magnitude of the communication system, the development of this improved planning tool is fully justified.

Comments on the adequacy of the formulation to solve any particular problem of the communication industry are not appropriate since the authors' purpose was only to sketch the possibilities. Actual problems contain a great number of special conditions. Fortunately, linear inequality systems are ideally suited to express commonly encountered conditions including those often approximated by nonlinear functions. Conversely, nonlinear functions (that satisfy certain convexity properties) are easily approximated to any degree of accuracy by linear inequalities.

I would like to comment briefly on recent developments that show promise of solving large-scale systems that might be encountered. Present electronic computer codes are of two types for solving (1) general-purpose problems and (2) transportation or distribution problems. The latter are linear programming problems with a very special structure. The authors' model also has a very special structure that is described as a kind of generalized distribution problem. In this connection Ford and Fulkerson[1] have proposed a method for generating paths through a network for multicommodity distribution problems that have direct application here. Recently the entire approach has been generalized (by Philip Wolfe and the discusser) into what appears to be a fundamental partitioning method which permits the separation of larger systems into component parts.

R. I. Wilkinson (Bell Telephone Laboratories, Inc., New York, N. Y.): The authors have undertaken to apply a new technique, linear programming, to the very old problem of interoffice trunk engineering. Their presentation is thought-provoking and deserves study by those concerned with the economical layout of complicated trunking patterns.

The paper states that in the interoffice trunking of communications systems, engineers have been "forced...to resort to various suboptimization schemes, many of which have been of the empirical or trial-and-error types." And that "This situation has in large part been caused by the lack of adequate mathematical and numerical techniques for analyzing and solving such problems." It is implied that these limitations are about to be lifted by the development of high-speed computers and linear programming "which has made many multivariable problems, heretofore thought unmanageable, numerically solvable."

One is compelled here to register a slight protest, since at least for most telephone interoffice trunk engineering, the "limitations" are not yet very far lifted by this paper. This is due largely to two unrealistic assumptions which the authors have made in order to apply linear programming methods to the problem. And unfortunately there is no apparent easy way to circumvent these assumptions.

First, the authors have assumed that every office will have exclusive use of a number of permanently connected circuits (including 0) to every other office in the area. However, in multioffice trunking plans of the type contemplated, there soon comes a time when some switching, either by built-up end-to-end connections, or by alternate routing through tandems, or both, is more economical than requiring that calls be completed only over permanently assigned direct circuits between each pair of offices.

Second, the paper sets up a radically different criterion of adequacy than has commonly, if not universally, been adopted for the dimensioning of American and foreign telephone systems. The paper proposes a single over-all objective of excellence which may roughly be stated: Form the maximum possible number of desired trunks, and use the minimum number of links to do it. This is an understandably attractive criterion to the engineer of complex systems; it is easy to visualize, it initially appeals to reason, is relatively simple to formulate mathematically, and, perhaps most engaging of all, leads to numerical specification of trunk quantities in a wholly mechanical manner.

However, in local systems most telephone companies adopt as a prime objective the giving of a relatively uniform good grade of service to each customer whatever the destination of his calls. The Kalaba-Juncosa solution says nothing about the grade of service being rendered in the system. Moreover, even if the simple meeting of some selected level of service in the aggregate were accomplished, it would hardly be a sufficient basis on which to allocate equipment and trunking facilities to individual routes. It is easy to show that, even in very elementary system layouts, better choices of trunk plan can be made (in the sense of more load carried and more uniform service given) than are obtained by the over-all optimization program proposed in this paper. There seems little reason to expect that better results would be obtained in more complex networks. Thus, contrary to the authors' introductory criticism, a certain amount of suboptimization appears to be a necessary requirement for attaining the most acceptable service in a given situation.

The relation between load offered to a group of devices and the service given (in the usual sense of proportion of calls lost or delayed, average length of delay, etc.) is seldom, if ever, linear. Therefore, simple optimization by the techniques of linear programming of some linear function of numbers of channels provided cannot generally be counted upon to yield the most satisfactory service—or better, the least unsatisfactory service—to the customers.

In spite of the afore-mentioned shortcomings, it is not inconceivable that the linear programming attack, or some allied method, might yet prove useful in certain communication traffic flow problems comprising a network of origination and termination points. Students of these problems should therefore be familiar with the method.

R. P. Thompson and **S. E. Mikkelsen** (The Pacific Telephone and Telegraph Company, Los Angeles, Calif.): When over 300,000 cable pairs are connected together to form about 150,000 voice paths linking more than 100 buildings, and with approximately 40,000 cable pairs being added each year, the problem of system design and system utilization becomes extremely difficult. This is the size of our problem in interoffice trunking at Pacific Telephone for the Los Angeles metropolitan area. Obviously the combinatorial possibilities are astronomical.

We first met Drs. Kalaba and Juncosa when they gave a talk on a mathematical model of the nation-wide toll switching network. We called their attention to the fact that the trunking in major cities might be a larger and more complex problem than nation-wide toll switching. We asked if they could adapt their mathematical model to this local interoffice trunking problem. This paper is their answer.

Their use of linear programming and the simplex method in their numerical experiments has created interest here in these techniques. In addition to their reference 2, the book, "Linear Programming and Economic Analysis," is useful as an introduction to this subject.[1]

We have been thinking of presenting to a computer a problem in linear programming that might get around the "restrictions" mentioned in the paper. To state the problem will require a little defining of terms.

Interoffice trunking means cable connections between central office buildings. (The word "stations" is used in the paper.) Each pair of conductors has a building at each end. We say connections between two specific buildings lie in a "route." ("Span" is used in some areas and "link" is used in the paper.) When there are many buildings in an area it is not practical to connect each building to all the others directly. We have about 350 routes between approximately 100 buildings. There are several grades, or types, of conductors with an average of about three in each route with a total near 1,000 route-grade combinations.

Traffic studies divide the voice paths needed into groups called "trunk groups." Each trunk group is between a pair of buildings and there may be many between the same pair differing in their requirements as to grade of service or equipment to be used. The required number of trunks is predicted by methods outside of the scope of this particular paper and are assumed to enter this problem as a given list of about 8,000 items. This is the same type of assumption used in the paper.

Since not all buildings are directly connected by routes, a great many of the trunk groups are served by built-up connections of routes in series, by means of jumpers. This is called a design. The design specifies the series connection of route grades, and there may be several designs for each trunk group.

Essentially, the idea is this: Forecasted growth, trunk group by trunk group, is bidding for spare pairs in the route grades called for in the designs for each trunk group respectively. How much of the growth of a given trunk group will work on each of its designs? Designs for different trunk groups will be competing for the same spare pairs in a given route grade. If a design fails in the bid, other alternate designs for the same trunk group will be tried and they may call on a different route or grade where there may be more spares.

This can be answered by linear programming once a criterion is established. This criterion can be the maximum number of trunks that can be connected, as was done in the paper, or the maximal number of spares, which was also done. Another possibility is that use of the plant which will produce the minimum total annual charge. This automatically favors hookups that use the shortest lengths and cheapest grades. Note that we do not solve the restrictions problem, but merely avoid it by predetermined designs each of which is equally suitable for its purpose although the cost may not be the same. This plan is no better than the designs offered into the system. The more designs, the greater possibility of optimizing.

With about 8,000 trunks groups, if only an average of two designs each is offered, this would yield 16,000 total designs. With 16,000 designs and 1,000 route-grades, a formidable linear programming matrix is created. Even with modified simplex methods and the latest superspeed computers, a still simpler method is needed. As Drs. Juncosa and Kalaba say, special computational algorithms will have to be developed. We thank them for their contribution toward solution of interoffice trunking problems.

MEMBER AIEE

A PILE OSCILLATOR is a device that periodically varies the neutron population in a nuclear reactor. The population change may occur as a localized variation in neutron density, or the density of neutrons throughout the reactor may be caused to vary in a systematic manner. Such a variation may be effected by a periodic oscillation of the multiplication constant, k_{eff}, of the reactor. The required changes in k_{eff} have been achieved in reactor oscillators by mechanical oscillations of either absorbers or reflectors located in or near the core.

The oscillator discussed in this paper produces the required change in k_{eff} by oscillation of an absorber placed near the reactor core. Since it is desirable that the variation in neutron population be sinusoidal in time, the absorber is designed accordingly.

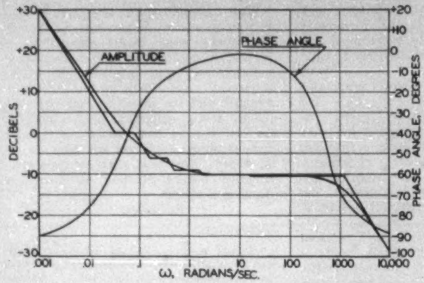
In order to use a pile oscillator, the amplitude of the sinusoidal changes in neutron population must be measured and the phase angle between neutron oscillations and oscillations of k_{eff} must be determined. Appropriate circuitry for making these measurements is also described in this paper.

Pile oscillators have been used for a variety of purposes. Quantities such as neutron absorption and scattering cross sections, delayed neutron characteristics, neutron mean lifetime in the reactor, effective resonance integrals, and the purity of uranium samples have been measured with pile oscillators. Pile oscillators have also been used to determine the dynamic stability of reactor systems and to measure power coefficients of reactivity.

The pile oscillator described in this paper has been designed for the University of Michigan's Ford Nuclear Reactor, a swimming-pool-type research reactor. The oscillator will be used both in connection with teaching laboratories and as a tool for studying the dynamic characteristics of the reactor system.

Paper 58-1329, recommended by the AIEE Nucleonic and Radiation Instrumentation Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted February 18, 1958; made available for printing September 9, 1958.

J. STONE and W. KERR are with the University of Michigan, Ann Arbor, Mich.



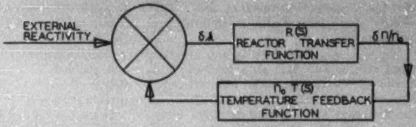


Fig. 1 (left). Calculated transfer function of the Ford Nuclear Reactor

Fig. 2 (above). Internal reactor feedback loop

Nomenclature

n = neutron population, neutrons per centimeter^3

k_{eff} = effective multiplication factor

$\delta k = k_{eff} - 1$

β = fraction of neutrons produced that are delayed; 0.75 per cent of the neutrons present in the reactor are delayed neutrons

τ = mean generation time of prompt neutrons, seconds; (2×10^{-6} second for the Ford Nuclear Reactor)

λ_i = decay constant of the ith group of delayed neutrons, second^{-1}. Five delay groups are considered

C_i = concentration of the ith group of delayed neutrons, precursors per centimeter^3

n_o = steady-state value of neutron population, neutrons per centimeter^3

δn = perturbation of neutron population

C_{i_o} = steady-state value of precursor population

δC_i = perturbation of precursor population

α_i = ith root of the polynomial (see equation 4)

$R(s)$ = reactor transfer function without feedback

$T(s)$ = temperature feedback function

$f(t)$ = signal plus noise

$\psi(t)$ = noise signal

I = value obtained by multiplying the ion chamber output signal by $\cos\frac{2\pi t}{T}$ and integrating for n complete cycles. Experimentally I will be the number of revolutions accumulated on the revolution counter during the n cycles that $f(t)$ is multiplied by $\cos\frac{2\pi t}{T}$. See reference 7

J = value obtained by multiplying the ion chamber output signal by $\sin\frac{2\pi t}{T}$ and integrating for n complete cycles. Experimentally it has a meaning analogous to I

Computation of a Transfer Function for the Ford Nuclear Reactor

A set of equations that can be used to describe the time behavior of the neutron population in a fission reactor operating near critical is given as follows:

$$\frac{dn}{dt}=\frac{(\delta k-\beta)}{\tau}n+\sum_{i}^{5}\lambda_i C_i$$

$$\frac{dC_i}{dt}=\left(\frac{\beta_i}{\tau}\right)n-\lambda_i C_i \qquad (1)$$

The second equation of the set describes the ith delay group precursor population. In a reactor 0.75 per cent of the neutrons originate from certain fission fragments, or precursors, and are not released at the time of fission. These neutrons are called delayed neutrons. Five such groups of delayed neutrons, and thus five precursor groups, are considered in the analysis to be given. The resulting equations form a set of six linear differential equations.

A useful transfer function for purposes of analysis is one that relates changes in neutron population, δn, to corresponding changes in multiplication constant, δk. If δk is assumed to vary with time, then the first differential equation has a time-varying coefficient. In much the same way that one determines the small signal response of electronic amplifiers, the response of the reactor neutron population, δn, to small variations of δk will be found. Let

$$n=n_o+\delta n \qquad (2)$$

$$C_i=C_{i_o}+\delta C_i$$

Here n_o is a steady-state value of neutron population and δn is a small excursion of neutron population about n_o. C_{i_o} and δC_i are similar descriptions of precursor population.

Substituting these expressions for n and C_i into the set of differential equations 1, discarding second-order terms, and using operational notation, produces

$$\frac{\delta n}{n_o\delta k}=\frac{1}{\tau s\left(1+\sum_{i}^{5}\frac{\beta_i}{(s+\lambda_i)\tau}\right)} \qquad (3)$$

Equation 3 can be written in the following form:

$$\frac{\delta n}{n_o\delta k}=\frac{\prod_{i}^{5}(s+\lambda_i)}{s\tau\prod_{i}^{5}(s+\alpha_i)} \qquad (4)$$

where α_i is the ith root of the fifth-order polynomial in the denominator that results from rationalizing the right-hand side of equation 3. See the Appendix.

Using values of β_i and λ_i given in reference 1 and assuming that τ for the Ford Nuclear Reactor is 2×10^{-6} seconds, from equation 4 the transfer function for the Ford Nuclear Reactor is obtained:

$$\frac{\delta n}{n_o\delta k}=\frac{(s+14.3)(s+1.61)(s+0.465)\times(s+0.154)(s+0.0315)}{2\times10^{-6}s(s+364.5)(s+14.21)\times(s+1.425)(s+0.336)(s+0.0775)} \qquad (5)$$

The amplitude and phase angle for equation 5 with $j\omega$ substituted for s are plotted in Fig. 1.

Use of the Oscillator in Determining Reactor Stability

As has been pointed out in the literature, a reactor operating near rated power can be throught of as a feedback system.[2,3] Not only are there feedback mechanisms inherent in the reactor itself, but an automatic control system connected to reactor control rods or to coolant pumps may form additional feedback loops.

As an example of an internal feedback mechanism, consider temperature effects. A small temperature change may vary the moderating and reflecting properties of the reactor core material as well as the geometrical shape. Such changes may introduce a change in k_{eff} which will in turn change n, the neutron population. Fig. 2 is a block diagram of a reactor with internal feedback loops. The closed-loop response of the system of Fig. 2 is

$$\frac{\delta n}{n_o\delta k}=\frac{R(s)}{1+R(s)T(s)n_o} \qquad (6)$$

where, as indicated in Fig. 2, $R(s)$ represents the reactor transfer function without feedback and $T(s)$ is a feedback term.

For experimental investigations it is useful to invert equation 6. There results:

Vol.
Pt. 1
1958

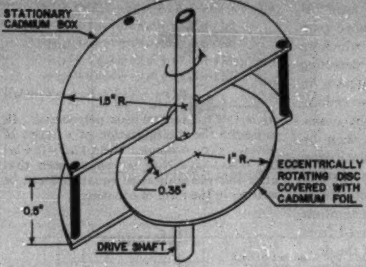

Fig. 3 (left). **Oscillating mechanism**

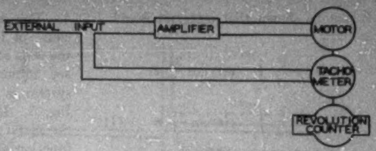

Fig. 4 (right). **Velodyne integrator**

$$\frac{n_0 \delta k(s)}{\delta n(s)} = \frac{1}{R(s)} + T(s) n_0 \tag{7}$$

By methods described in reference 4 the quantities in equation 7 can be determined and the stability of the system investigated. The following procedure may be followed.

1. Operate the reactor at low power so that $T(s)n_0$ will be small compared to $1/R(s)$. Vary δk sinusoidally over a range of frequencies, from 0.001 to 100 cycles per second in the case of the Ford Nuclear Reactor, and measure δn with the circuitry described in the next section of this paper. If the power level is low enough $1/R(s)$ may be computed from these data. The experimental values may be checked with that given by equation 5.

2. Operate the reactor at a higher power level. After allowing the system to reach temperature equilibrium determine the reactor response over the same frequency spectrum as in step 1. As shown by equation 7 these data should allow computation of the quanity $1/R(s)+T(s)n_0$.

3. Instability will exist if for some frequency and some n_0 the quantity $1/R(s)+T(s)n_0$ is equal to zero. This may be investigated by plotting the transfer function $(n_0\delta k)/\delta n$ as a complex number for the frequencies at which data are taken. At a given frequency the vector difference between the transfer function at very low power and at some higher power is the quantity $n_0T(s)$. If this vector can be extended to go through the origin then there exists some power level at which the reactor system will be unstable. This follows from the fact that at a given frequency the phase angle of $n_0T(s)$ is independent of the reactor power level, n_0.

Mechanical and Electrical Design

The Ford Nuclear Reactor uses the BSF (Bulk Shielding Facility) type of fuel elements in a matrix surrounded by graphite reflecting elements. It was felt that it would be most convenient to insert the the oscillating absorber into a position normally occupied by a reflector element.

The design of the oscillator involved computation of the δk introduced by the oscillation of an appropriately shaped absorber in the reactor. Calculations were made using 2-group perturbation theory. These showed that about 0.5 gram of cadmium foil placed in the outer row of graphite reflectors would produce a change in k_{eff} of 10^{-5}; see reference 5. Since derivation of the reactor transfer function assumes a small δn, the oscillator was designed with this in mind. Other calculations showed that the δk produced by the moving absorber of the oscillator would not be much different from that produced by the same quantity of a stationary absorber.[5]

An eccentrically mounted circular disk covered with cadmium foil and rotated with constant angular velocity in and out of a fixed cadmium box was designed to vary k_{eff} sinusoidally. By choosing the eccentricity such that the distance between the center of the disk and drive shaft is 0.35 r, where r is the rotating disk radius, the exposed cadmium area, and thus k_{eff}, will vary harmonically. Fig. 3 shows the mechanical design of the absorber.

For detecting the changes in neutron population, a parallel-circular-plate boron-coated ionization chamber is used.

Both the random nature of the detection process used in the ionization chamber and the randomness of the multiplication process in the reactor introduce noise along with the desired signal. In order to separate the approximately sinusoidal signal from this noise a correlation technique has been used. This is simply the multiplication of the signal by sine and cosine functions of proper frequency. This is accomplished by employing sine and cosine potentiometers driven at the same frequency as the mechanical oscillator. The output signal of the ionization chamber, after amplification, can be represented as

$$f(t) = A\cos\left(\frac{2\pi t}{T} - \theta\right) + \psi(t) \tag{8}$$

where

A = signal amplitude
T = the period of the true signal and of the oscillating δk
θ = the phase shift of the signal with respect to the oscillating δk
$\psi(t)$ = the noise signal

If this function is multiplied by $\sin 2\pi t/T$ or $\cos 2\pi t/T$ and integrated for n complete cycles there results:

$$I = \frac{2}{nT}\int_0^{nT} f(t)\cos\frac{2\pi t}{T}\,dt$$

$$J = \frac{2}{nT}\int_0^{nT} f(t)\sin\frac{2\pi t}{T}\,dt \tag{9}$$

If $f(t)$ is represented as

$$f(t) = A\left(\cos\frac{2\pi t}{T}\cos\theta + \sin\frac{2\pi t}{T}\sin\theta\right) + \psi(t) \tag{10}$$

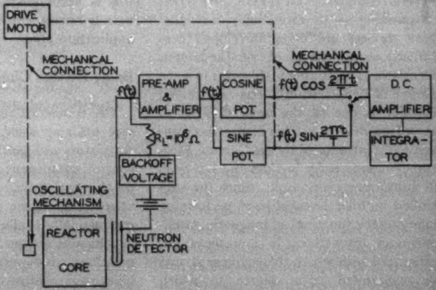

Fig. 5. Detecting circuitry

It can be shown that integrals I and J are now

$$I = A\cos\theta + \frac{2}{nT}\int_0^{nT}\psi(t)\cos\frac{2\pi t}{T}\,dt$$

$$J = A\sin\theta + \frac{2}{nT}\int_0^{nT}\psi(t)\sin\frac{2\pi t}{T}\,dt \qquad (11)$$

The integrals involving the noise terms in equation 11 are on the average zero since the noise is assumed to be nonperiodic. For each oscillation frequency and its corresponding period, T, is found a certain amplitude and a certain angle

$$A = \sqrt{I^2 + J^2}$$

$$\theta = \tan^{-1}(J/I) \qquad (12)$$

The operations described by equations 9 are achieved by the use of the sine and cosine potentiometers.

The integrator chosen is a type that has been used in pile oscillator instrumentation by Breton.[6] It consists of a d-c split-field motor whose angular velocity is proportional to the applied voltage. The angle of rotation of the motor shaft over a certain time interval is thus proportional to the integral of the signal imposed on the field control winding. On the same shaft are connected a revolution counter and a tachometer. The output voltage of the tachometer is fed back to the motor as shown in Fig. 4. This type of integrator is used because of its excellent performance over the wide range of frequencies in which we are interested.[7] The entire detecting system is shown in block diagram in Fig. 5. In the experimental procedure, the signal $f(t)$ is multiplied by the cosine function for 10 minutes and then by the sine function for a similar time. By noting the number of revolutions recorded on the revolution counter in the integrator, the phase and magnitude of the δn signal can be ascertained from equations 12. The frequency of the driving function δk can be changed by changing gear ratios (not shown in Fig. 5) and driving motor speed. As can be seen from Fig. 5 the sine and cosine potentiometers as well as the mechanical oscillator all move at the same frequency.

Appendix

Equation 3 may be written

$$\frac{\delta n}{n_0\delta k} = \frac{1}{s\left[\tau + \frac{\beta_1}{s+\lambda_1} + \frac{\beta_2}{s+\lambda_2} + \frac{\beta_3}{s+\lambda_3} + \frac{\beta_4}{s+\lambda_4} + \frac{\beta_5}{s+\lambda_5}\right]}$$

Rationalizing the denominator of this equation results in the following fifth-order polynomial:

$$\begin{aligned}\tau[(s+\lambda_1)(s+\lambda_2)(s+\lambda_3)(s+\lambda_4)(s+\lambda_5)+\\ \beta_1(s+\lambda_2)(s+\lambda_3)(s+\lambda_4)(s+\lambda_5)+\\ \beta_2(s+\lambda_1)(s+\lambda_3)(s+\lambda_4)(s+\lambda_5)+\\ \beta_3(s+\lambda_1)(s+\lambda_2)(s+\lambda_4)(s+\lambda_5)+\\ \beta_4(s+\lambda_1)(s+\lambda_2)(s+\lambda_3)(s+\lambda_5)+\\ \beta_5(s+\lambda_1)(s+\lambda_2)(s+\lambda_3)(s+\lambda_4)]\end{aligned}$$

α_i is the ith root of this polynomial. Π_i indicates the multiplication of a series of terms. For example, $\Pi_i{}^3(s+\lambda_i) = (s+\lambda_1)(s+\lambda_2)(s+\lambda_3)$. Now it can be seen that after this rationalization equation 3 can be written in the form of equation 4.

The Controlled Rectifier: Key to the Continuing Control Renaissance

J. D. HARNDEN, JR.
ASSOCIATE MEMBER AIEE

THE SEMICONDUCTOR art is expanding at an exceedingly fast rate. New devices are being developed continually so that the use of even the famous transistor is beginning to decrease in some areas of application. The controlled rectifier is one of the most exciting of these new devices. This device was commercially introduced by the General Electric Company early in 1958 and has been in production ever since. Since the controlled rectifier is capable of performing many of the functions of magnetic amplifiers and thyratrons, it represents another tool with which the engineer should be acquainted. The degree to which this is accomplished will determine the new horizons which are possible in the application area.

Basic Device Characteristics

The controlled rectifier is a silicon device utilizing some of the properties of transistors and rectifiers to produce a new control component somewhat analogous to the thyratron. The device circumvents some of the problems surrounding commercially available power transistors, in achieving greater voltage ratings, faster switching times, and in being capable of higher temperature operation. The basic device consists of four regions, p-n-p-n, as shown in Fig. 1. While the device appears to be somewhat like a hook transistor in that both have four regions, its method of operation and application is markedly different, and it must be treated as an entirely new device. The basic anode-to-cathode characteristic is also shown in Fig. 1, which reveals the fundamental switching action.

In addition to the diode method of control, by far the greatest potential surrounds the use of the third element for triggering. Using this gate method of control, the controlled rectifier has a minimum power gain (ratio of output power to input power) in excess of 150,000 with switching times of the order of 1 microsecond. This power gain assumes

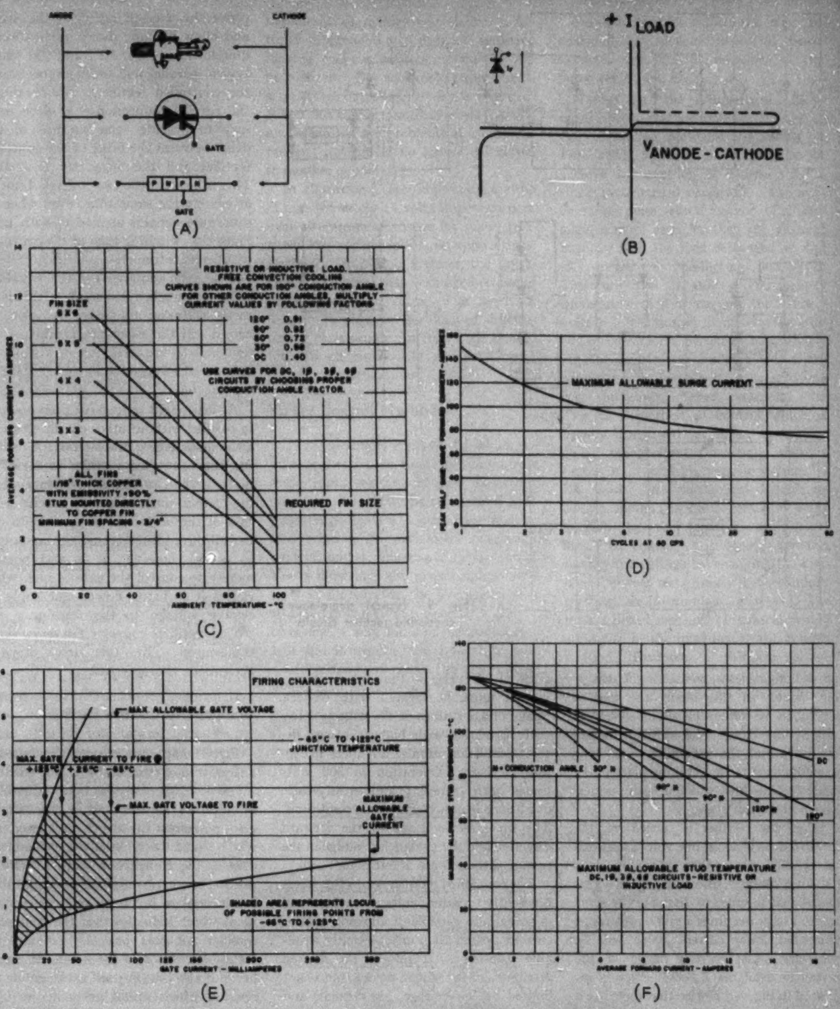

Fig. 1. ZJ-39A controlled rectifier characteristics. A—Gate. B—Anode-cathode. C—Required fin size. D—Maximum allowable surge current. E—Firing characteristics. F—Maximum allowable stud temperature

continuous gate drive. For pulse methods of triggering, the power gain should be re-evaluated, depending on the pulse width. The device exhibits a "deionization time" which is somewhat analogous to that which takes place in thyratrons. This time is in the order of three times the turn on time. The possibility exists that the controlled rectifier can be turned off, but it may not be desirable to design the unit to allow utilization of this characteristic. However, with this potentiality, the device would become very analogous to the ideal switch in that a pulse could turn the rectifier on, allowing it to remain in a highly conductive state in the absence of control power, and to be turned off, reverting to its open condition by applying negative signal information for a short period of time.

It must be emphasized that the device does not require continuous signal excitation as does a transistor. The transistor is a proportional device which has im-

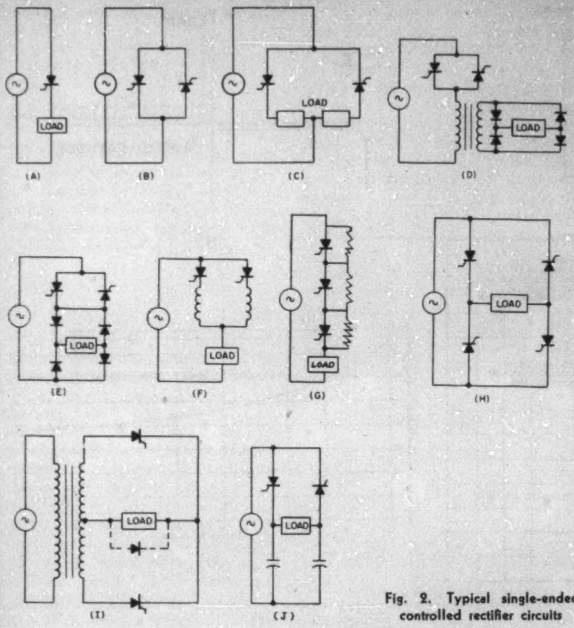

Fig. 2. Typical single-ended controlled rectifier circuits

proved properties when used in the switching mode. In this mode, the unit is forced to be either closed or open by driving the base. The switching losses are large and the switching times long in comparison to those taking place in the controlled rectifier, which actually undergoes a change of state.

When the rectifier is turned on, the forward drop is about one volt or approximately 20% greater than the voltage drop for an ordinary silicon rectifier. This means that in order to dissipate the same amount of power from a given package, a somewhat lower current value will be necessary. The current rating of the presently available *ZJ-39A* series is indicated in Fig. 1. Notice that there are a number of current ratings, depending on the application. The allowable current depends on the size of the unit, i.e., the junction area, the method and effectiveness of cooling, and the per cent ON time of the current wave form.

Like any power semiconductor device, the time constant of the junction is of importance during transient conditions, while the thermal heat sink must take care of steady-state losses. The time constant of the junction is less than a half-cycle of 60 cycles so that transient protection must be treated with respect. Peak voltage ratings of 400 volts are presently available with higher voltage designs paralleling similar advances in regular rectifiers. Operation to 500 volts under both transient and steady-state conditions is possible for some conditions. The breakover voltage in the forward direction and the avalanche voltage in the reverse direction are about equal.

The controlled rectifier seems to possess inherently greater voltage ratings and is potentially capable of allowing greater current ratings than any presently available transistor. It retains the desired attributes of the silicon device, but is not limited by low-voltage, low-current, and high-saturation resistance as is common for commercially available transistors. It is obviously only a matter of time before controlled rectifiers will be available in ratings similar to those of ordinary silicon rectifiers, thereby competing with and replacing saturable reactors, magnetic amplifiers, thyratrons, and ignitrons in many applications.

It is possible to parallel and also to connect units in series, as well as using them in multiphase connections to improve the over-all rating of the system and allow meeting many application requirements. Figs. 2(F) and (G) show a typical parallel and series connection for the controlled rectifier. Notice that in the parallel connection it is often necessary to provide some method of time delay between the firing of one controlled rectifier and the firing of other units. This is because the two units will not fire at exactly the same time, even when the same gate signal is applied to both units. Since the switching time of the controlled rectifier is extremely fast, the number of volt-seconds required for the equalizing inductors is relatively small, if this is the method chosen to delay the switching action. If this reactance is omitted, the first unit to fire could act as a short circuit on the second unit, preventing its turning on.

At least eight units have been operated in parallel without other circuit elements, after some degree of selection. Connecting the controlled rectifier in series requires a small amount of resistance-shunting of each unit, or a very careful selection of the units. It is possible to control all three units to cause the breakdown to occur; however, it is also possible merely to control the gate of one, which causes it to break down, and apply excessive voltage to the remaining controlled rectifiers connected in series across the source. They then break down on their diode characteristic.

Competitive Control Device

Fig. 3 compares a saturable reactor and a thyratron of comparable rating with the *ZJ-39A*. Not only is the controlled rectifier far smaller and lighter, but it also possesses the other characteristics which have been briefly outlined. Of course, the comparison with a self-saturating magnetic amplifier of equal rating would need to involve a rectifier complement which indicates that the controlled rectifier not only basically replaces the saturable reactor in the magnetic amplifier, but also that in itself it can act as the rectifier which would normally be used in such an application. The controlled rectifier is capable of a high degree of efficiency since only one volt is lost or not delivered to the load for supply voltages approaching 400. In a magnetic amplifier, there are several factors which prevent the full application of voltage to the load consisting of the resistance of the gate windings and the reactance of the inductive circuit. The magnetic amplifier must have sufficient turns to prevent saturation of the core on the applied volt-

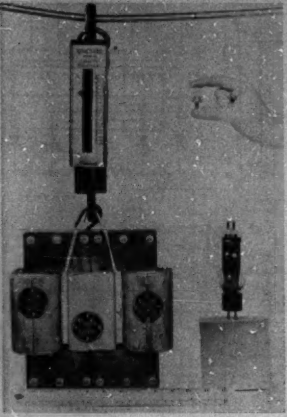

Fig. 3. Amplistat reactor, thyratron, and ZJ-39A controlled rectifier of approximately equal power rating

age, and these turns must be capable of carrying full load current without overheating. These two factors cause the amplifier to be a relatively large device. The gain of the magnetic amplifier is, of course, variable depending on the amplifier's response time, frequency, etc. The controlled rectifier, on the other hand, is not capable of interchanging gain for response, being basically a fixed-response device. For all intents and purposes in industrial control systems, the transfer function of the controlled rectifier may be considered merely as a gain stage with no transport lag, phase shift, or ramp function. As the carrier frequency approaches the inherent switching time of the device, there is some transport lag which should be considered.

All magnetic methods of amplification need not be static. An amplidyne is an example of a rotating amplifier. Two virtues of the amplidyne are that the output varies in magnitude, (i.e., it is not phase-controlled) and that the output is basically push-pull or polarity-reversing. In a sense, an electromagnetic relay is also an amplifier. In addition to size, weight, and environmental specifications, general relay requirements are for lowest input power, highest contact rating, and fastest operating speeds. Clearly, a switch of the electromagnetic type is incapable of matching the response of the inertialess controlled rectifier. The minimum gating power is lower than many so-called sensitive relay requirements at present, and as the family of ratings materialize, sensitivity approaching the most sensitive moving coil contact-making meters will be realized. For each pole requirement, a separate controlled rectifier is required. When this device is used as a relay, shock and vibration are problems of a different nature, and life is no longer calculated in number of operations.

In thyratrons, the high-voltage drop of approximately 15 volts imposes a poor over-all system efficiency for many relatively low-voltage industrial applications. Certainly for 28-volt systems, the thyratron is at a great disadvantage because of its high forward drop. The need for filament supply power, delayed application of plate supply, and relatively limited life are all necessarily associated with thyratron applications.

Power Control Methods

There are many methods by which the voltage across a load may be varied from some input voltage source. Generally speaking, these may be categorized as 1. phase-angle control, 2. time base modulation control, 3. mechanical magnitude control, and 4. impedance ratio control. Fig. 4 illustrates the phase-angle control method for varying the average voltage to a load from a given a-c carrier. This is, of course, a very familiar method of control and it results in a typical transfer characteristic of input versus output which may be expressed by

$$I=\frac{E}{R}\,\frac{1+\cos\alpha}{2}$$

Further, such a waveform may be analyzed for various ratios of peak, average, and rms, as functions of the firing angle; see Fig. 5.

Notice that the symmetrical phase-angle control method requires the use of two controlled rectifiers, as shown in Fig. 2(B), whereas it is possible to achieve this method of control with a single symmetrical transistor. The synchronous pulse width method of phase-angle control requires that the element in series with the load be turned on and off during a conducting half-cycle. Therefore this is not a particularly common method of varying the average voltage. The time base modulated methods of control are becoming increasingly popular due to the availability of sharp saturating devices such as square-loop core materials, Zener rectifiers, etc. This is a method of control which is usually construed to mean generation of an independent time base, thereby producing a variable average voltage to the load. The mechanical magnitude control method is quite common, being typified by the variable transformer idea. Of course, it is equally possible to vary the voltage by changing the coupling between the primary and secondary windings in a number of ways. The least utilized method of control would appear to be the impedance ratio control method. Examples of this are voltage doubler circuits and circuits using a resonant type of variable voltage source. While single-phase representations have been considered, it is obvious that the

General Circuitry

To attempt to list all the possible applications of the controlled rectifier would be almost impossible. However, it is possible to outline briefly the more obvious applications, including such things as control of heaters, control of lamps, motor and generator control, static switching, static excitation, pulsers, circuit protection, servo amplifiers, inverters, and frequency changers. In any application, it must be borne in mind that the controlled rectifier can act only as a switch, i.e., it is either on or off, and there are a few applications in which the device is not applicable directly. In this paper, an attempt will be made to summarize briefly some of the circuitry which might be used with controlled rectifiers. The circuit potentialities and methods of application follow closely those of thyratrons and magnetic amplifiers.

The bridge circuit shown in Fig. 2(H) provides inherent commutation protection, which is as desirable with controlled rectifiers as it is with other types of amplifiers. In the center tap circuit of Fig. 2(I), an auxiliary diode is usually required. In the case of normal rectifier circuitry, the peak inverse voltage ratings required in the circuit connections will follow and parallel directly the requirements in normal rectifier circuitry. Fig. 2(B) is of additional interest because it provides some degree of inherent protection for the semiconductors in the presence of abnormal voltage pulses and surges on the voltage distribution system. Since the rectifiers are connected in parallel and in an inverse direction, any excessive voltage transient will cause one or the other to break down on its diode characteristic and allow the fault to pass on to the load, thereby protecting the reverse characteristic of the nonconducting controlled rectifier. Typical push-pull circuits are indicated in Fig. 6, while multiphase configurations are diagrammed in Fig. 7. The controlled rectifier is a radically new device from the point of view of application because it affords a duality of control methods. It is capable of being gate-controlled, as well as possessing an avalanche characteristic from anode to cathode.

As an example, it would be possible to utilize this device so that in a control system the breakdown of the diode characteristic would take place for voltages greater than a certain value and for values less than this; then, it would be possible to gate control the output. Thus, this device could be used as a limiting element in a feedback system for clipping and control purposes. A simple relaxation oscillator using the diode characteristic is shown in Fig. 8(A). Normally, in such a circuit, the gate would not be used. However, data indicate that by using the gate and allowing negative current to flow, the breakover can be changed, thereby changing the frequency of oscillation.

The circuits shown in Fig. 8(B) and (C) are very similar in nature. These two circuits operate from a d-c source and provide alternating conduction to the split load which can either be resistive or consist of a transformer. In operation, basically, the controlled rectifiers are alternating in their conduction half-cycle, depending on the nature of the input information. In (B), successive pulses cause the load current to flow in alternate branches of the split load. Once triggered into a conducting condition, no further gate power is required and no further change in load will take place until another pulse is applied to the system. In Fig. 8(C) this characteristic is utilized in a simple parallel-inverter circuit. The power requirement for the synchronizing signal is small in this type of circuit. While it is a simple inverter circuit, it is relatively restricted as to its usefulness.

Of course, more complex circuits will

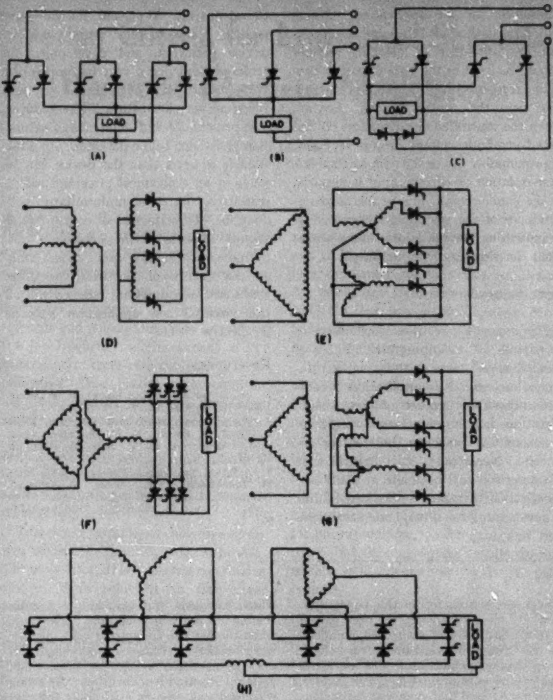

Fig. 7. Typical multiphase controlled rectifier circuits

find wide utilization of controlled rectifiers for improving inverter performance. Notice that this method of inversion depends on external circuit parameters for commutation in contrast to the inherently commutated transistor-saturating core type of inverter. Since the controlled rectifier is a high-power high-voltage device, applications to inverters of high power rating in all phase combinations is an ideal application. Already a number of high-power inverters have been constructed. Indications are that higher frequency operations will be possible than previously with either transistors or thyratrons because of the inherently faster deionization time. In the broad sense, inversion is but a small segment of a technological area, encompassing frequency changers and converters as well. Likewise, many systems cannot be uniquely classified since they may combine several modes of operation, depending on load conditions. In some instances, it may be advantageous to combine a converter with an inverter to achieve best over-all performance with savings in inverter size and weight.

Gating Circuitry

The circuitry necessary for triggering controlled rectifiers is a function of the application requirement and the performance desired. It is possible to use semiconductor preamplifiers in any number of circuits for triggering, phase shift control, etc., in addition to normal-phase shifters, firing circuits, and direct currents The gating action can also be produced by direct injection of energy (such as light) into the crystal itself. In many applications, it appears that the use of magnetic circuitry in the gate circuit will be advantageous because of the isolation which the magnetic circuitry provides inherently, and the large range of phase-angle control and large ratio of maximum to minimum currents obtainable with the use of square-loop core materials. In addition, magnetic devices provide an ideal mechanism for amplifying d-c signals down to relatively low levels such as 10^{-8} watts, or lower, over wide ambient and environmental ranges. The actual wavefront of the load current will usually be faster than that of the gating device, due to the fast firing time of the controlled rectifier. It should also be emphasized that the controlled rectifier imposes no further delay on the over-all system performance. Virtually all of the delay, phase shift, and dead time will be contributed by whatever device is used to gate the controlled rectifier.

In contrast to most conventional magnetic amplifier circuits which produce full output in the absence of signal, the controlled rectifier is a fail-safe device; i.e., in the absence of a signal, the output is zero. The on-to-off ratio of the controlled rectifier is exceedingly high. The average minimum holding current is approximately 10 milliamperes with peak load currents reaching 30 amperes or more. The minimum holding current is analogous to the conduction voltage drop in the thyratron since, if the current falls below this value, the controlled rectifier will revert to the open condition. In the open condition, the leakage currents in both the forward and reverse directions will be approximately the same as those found in a silicon power rectifier of comparable rating. Notice also that this as

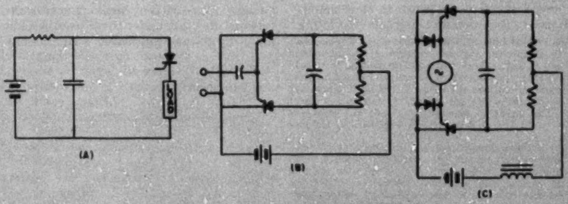

Fig. 8. Typical d-c controlled rectifier circuits

well as other parameters will vary with temperature as does a silicon rectifier. Unlike the magnetic amplifier, exciting current is not required to flow prior to the actual beginning of conduction. Full control is retained until the actual time of triggering. However, there is a finite leakage current which flows in both directions which might be considered somewhat analogous. The amount of leakage depends on the quality of the unit, the temperature, etc.

The gate signal must be greater than approximately one volt to overcome the inherent voltage drop of the lower p-n region of the controlled rectifier. The other requirement is that sufficient current be injected into the lower positive region to cause the avalanche to produce itself at the inner n-p region in the 4-layer construction. It requires approximately 15 milliamperes for this triggering action to take place. Certain precautions should be taken with regard to the gate circuit in order to prevent application difficulties. First, the lower p-n region is a relatively poor rectifier with a low forward-to-reverse ratio of resistance (about 4 to 1). Therefore, for a-c applications, during which the cathode will become positive, a limiting resistance or blocking rectifier should be used in the gate circuit to prevent excessive current flow out of the gate lead into the control circuit. Second, when the controlled rectifier turns on, the gate-to-cathode voltage drop is very low, approximately 0.2 or 0.3 volt, so that further isolation or current limit is required in the gate circuit. The temperature dependence of the gate is indicated in Fig. 1, indicating the need for a sharp wavefront for widely varying ambients.

Conclusions

The controlled rectifier would seem to be capable of revamping any number of control applications with a marked degree of success. New applications heretofore impossible because of size, shock, vibration, heater power, and weight restrictions will challenge the creative engineers. Necessarily, it is natural that a comparison will be made in many applications with regard to the capabilities of power transistors, magnetic amplifiers, thyratrons, etc. At present, the controlled rectifier seems to offer more range for device perfection and development in terms of achieving a very high operating voltage and large current ratings, and therefore very low saturation resistances. The present *ZJ-39A* device has a saturation resistance below 0.2 ohm. In addition, it appears that the device can be made at an economical price and with a reasonable degree of uniformity in production. These factors of course, are of utmost importance in choosing a new component for circuit application. Only as the family of controlled rectifiers grows and new units are released will all the potential new application horizons be clearly visible.

Discussion

F. W. Gutzwiller (General Electric Company, Clyde, N.Y.): Mr. Harnden admirably achieves the twofold objective of introducing a new type of semiconductor power device to the AIEE and discussing in detail some of the widespread technical ramifications and effects that this new device will have on the uses and control of electrical power. He emphasizes the outstanding advantages of the silicon controlled rectifier over other types of devices that control relatively large blocks of power by switching action. In comparing the controlled rectifier with other devices, it is worth recognizing that the downward price trend of semiconductors counteracts general economic forces that tend to raise the cost of other types of devices. This economic factor combined with the advantages listed in the paper can be reasonably expected to make the controlled rectifier the key that unlocks the tremendous potential for more refined, precise control of electric power in the consumer and commercial fields in some similar degree to that already being achieved in the industrial and military fields.

Since the submission of this paper, substantially more experience has been gained in series operation of controlled rectifiers. The variation of forward breakover voltage with junction temperature can be quite large in devices of present-day manufacture. It has been found that even with meticulous matching of forward blocking characteristics and the other parameters that affect junction temperature, satisfactory series operation without external forcing means requires such drastic voltage derating to prevent misfiring as to make this approach impractical. On the other hand, the use of shunt resistors for forced voltage sharing, as suggested by Mr. Harnden, has proved very satisfactory.

In typical rectifier applications, over-all circuit efficiency is reduced by less than 0.3% by the addition of shunt resistors.

Because of the variation in forward breakover voltage just discussed, it has also proved generally unsatisfactory to fire a series string of controlled rectifiers simply by controlling the gate of one of the cells. Such a string must be able to withstand full circuit voltage without breaking over in the forward direction under conditions of maximum junction temperature which occurs when maximum load current flows under the highest ambient conditions. However, when the devices are started cold, the forward breakover voltages of individual cells may be as much as two or three times greater. Under these conditions the string will not break over by controlling the gate of only one cell. For reliable control, multiple secondaries on a small pulse transformer can be used to feed an electrically isolated control signal to each of the individual cells.

In measuring the forward conductivity of the controlled rectifier, Mr. Harnden uses the transistor term "saturation resistance." Although such a term may have some significance over a limited current range, it is worth noting that the controlled rectifier does not have a characteristic approaching true resistance until load current levels reach several times normal. The *ZJ39A* device described approaches a dynamic resistance of approximately 0.01 ohm at 100 amperes. This low level of dynamic resistance at high current levels is a unique advantage over power transistors of the same general current rating, and it has particular significance in pulse-type applications.

Design Criteria for Low-Level Second-Harmonic Magnetic Modulators

E. J. KLETSKY
NONMEMBER AIEE

MAJOR difficulties are encountered when d-c amplifiers are used to amplify low-level low-frequency signals. These difficulties are mainly problems of zero-drift and noise. One of the most successful techniques in circumventing the drift and noise problems is to convert the low-frequency intelligence to a frequency permitting conventional a-c amplification. The means for accomplishing the frequency conversion have been mainly mechanical: choppers, vibrating capacitors, and similar devices. These devices, by their very nature, must be operated at relatively low sampling rates and are subject to the usual failures of moving equipment.

This paper presents an analysis and design criteria for the magnetic modulator. The modulator, as a frequency-conversion device, offers solutions to the aforementioned problems. It converts low-level low-frequency signals into amplitude-modulated suppressed-carrier outputs. The device has extremely low inherent zero-drift, wide frequency range extending down to direct current, and considerable power gain. Along with these electrical characteristics, the modulator has no vacuum tubes, no moving parts, nor does it require critical adjustment; hence it is extremely rugged and practically maintenance-free.

In spite of the modulator's desirable features, it has not found widespread application. A glance into the history of the magnetic modulator indicates why its striking characteristics have not been previously exploited, and what is needed in order to exploit these characteristics more fully.

The basic operating principle of the magnetic modulator has been known for many years. In the early 20's the Bell Telephone Laboratories carried out preliminary investigation of the modulator.[1] However, the lack of magnetic materials with high permeability, and the advent of a new and interesting device, the vacuum tube, caused research on the magnetic modulator to bog down. For the next 15 or 20 years, the device lay dormant.

During World War II the modulator was re-examined. With the aid of new magnetic materials, it was developed into an extremely sensitive air-borne magnetometer for use in submarine detection and geological survey.[2] Some basic analytic expressions for the characteristics of the modulator were formulated at that time, but these are not sufficiently general to be useful in the over-all design of magnetic modulators.

In 1950 Williams and Noble[3] indicated that the fundamental limitation on signal level was the presence of Barkhausen noise inherent in the core material. This established the lowest detectable signal level at about 10^{-19} watt per cycle of bandwidth.

In 1951 Manley,[4] of the Bell Telephone Laboratories, set forth some expressions for output voltage, power gain, and rise time; but once again the results do not readily lend themselves to design procedures.

Thus the need for a general analysis of the operation of the magnetic modulator is felt. The analysis presented here is the result of a combined physical, geometrical, and mathematical interpretation of modulator operation. Experimental work has been carried out to verify the analytic expressions. On the basis of the analytic and experimental work some general design considerations are discussed.

Nomenclature

A = core cross section, square centimeters
a = voltage amplitude, volts
B = flux density, gauss
B_s = saturation flux density, gauss
E_2 = peak value of second-harmonic voltage, volts
e_0 = instantaneous value of output voltage, volts
f = frequency, cps (cycles per second)
F_1 = modulator figure of merit, $\sec^{-1}$ (second^{-1})
G = power gain, dimensionless
H = magnetizing force, oersteds
H_c = coercive force, oersteds
H_m = peak value of excitation magnetizing force, oersteds
H_0 = magnetizing force produced by signal, oersteds
H_s = saturation value of magnetizing force, oersteds
I_m = peak value of excitation current, amp (amperes)
I_0 = signal current, amp
i_e = instantaneous value of excitation current, amp
i_{sig} = instantaneous value of signal current, amp
L = signal winding inductance, henrys
l = mean core length, centimeters
N_0 = number of turns in output winding, turns
n = order of harmonic component, dimensionless
P_{in} = signal power input, watts
P_o = useful power output, watts
R_L = load resistance, ohms
R_w = signal winding resistance, ohms
T = period of excitation, sec
t = general time variable, sec
t_d = time delay due to hysteresis, sec
t_r = rise time of trapezoidal excitation, sec
α = slope of flux density, gauss per sec
β = phase shift due to signal, rad (radians)
δ = width of output voltage pulses, sec
μ_a = average permeability of core, gauss per oersted
μ_m = maximum permeability of core, gauss per oersted
τ = time constant, sec
ψ = slope of trapezoidal excitation, oersted per sec

Mathematical Analysis of Operation

PRINCIPLE OF OPERATION

In its most general form, the magnetic modulator consists of a single high-permeability toroid wound with separate windings for excitation, signal, and output. The device differs from an ordinary modulator in that the even harmonics of the excitation (carrier) are amplitude-modulated by the signal while the carrier itself is not. Any one of the even harmonics can be employed as the output or the summation of several or all even harmonics can be used.

If the waveform of the excitation current has zero-axis symmetry, then the resulting core flux (and hence the voltage induced in the output winding) con-

HIGH IMPEDANCE EXCITATION SOURCE
HIGH IMPEDANCE SIGNAL SOURCE

Fig. 1. High-impedance modulator

tains only fundamental and odd-harmonic components because of the odd-symmetrical character of the hysteresis loop of the core. If a signal is applied to the signal winding, even-harmonic components also appear in the output. For small values of signal, a linear relation exists between the signal and the amplitude of the even-harmonic components. The sense of the signal is preserved in the phase of the output with respect to the excitation.

The extremely low zero-drift of the modulator arises from the symmetrical character of the hysteresis loop around which the device operates. This symmetry is not disturbed by either temperature or frequency.

There are many modes of operation of the modulator. Excitation and/or signal may be supplied from voltage or current sources or from sources of finite impedance. The output may be taken as a voltage or a current. A single winding may serve two or more functions, thus allowing winding space to be used to best advantage.

The analysis which follows treats the case where both signal and excitation sources are of high impedance and the output is taken as a voltage.

NO-SIGNAL OPERATION

The circuit to be analyzed is shown in Fig. 1. Functionally the output voltage is given by

$$e_o(t) = -N_oA\frac{dB}{dt} = -N_oA\frac{d}{dt}\,[B(H)]$$

where

$$H = f(i_e) \tag{1}$$

In order to set up useful mathematical relations for the operation of the modulator, it is necessary to describe analytically the nonlinear flux-current characteristic. A piece-wise linear approximation[5] incorporating maximum permeability, zero saturation permeability, and neglecting hysteresis has been used.

Fig. 2 shows a geometrical interpretation of equation 1 in which this approximation to the flux-current characteristic is used. Sinusoidal excitation current can be approximated by the trapezoid shown for simplicity in the analysis. The validity of this approximation is borne out experimentally.

Fig. 2 indicates that if the excitation current is trapezoidal, the flux is also a trapezoidal function of time. The output voltage, found from the time derivative of the flux, consists of the sum of a set of positive pulses and a similar set of negative pulses shifted π rad. A Fourier series expansion shows that the output voltage is

$$e_o(t) = \sum_{n=1}^{\infty} \frac{2a}{n\pi}\,[1-(-1)^n]\,\sin\frac{n\pi\delta}{T}\,\cos\frac{2n\pi t}{T} \tag{2}$$

Note that $e_o(t)$ contains only odd harmonics, since when n is even, the expression goes to zero.

OPERATION WITH SIGNAL

When a signal I_o (corresponding to a magnetizing force equal to H_o) is applied, the output is altered as shown by the dotted lines in Fig. 2. With signal, the positive set of pulses is advanced by amount β rad and the negative set retarded by the same amount. Under these conditions, the output voltage is

$$e_o(t) = \sum_{n=1}^{\infty} \frac{2a}{n\pi}\sin\frac{n\pi\delta}{T}\left\{[1-(-1)^n]\cos n\beta \times \cos\frac{2n\pi t}{T} - [1+(-1)^n]\sin n\beta\,\sin\frac{2n\pi t}{T}\right\} \tag{3}$$

The geometrical parameters a, δ, and β of equation 3 can be replaced by electrical equivalents derived from the geometry of Fig. 2:

$$\tan\alpha = \mu_m \tan\psi = \mu_m\frac{H_m}{t_r} \tag{4}$$

$$\delta = 2\frac{H_s}{\tan\psi} = 2\frac{H_st_r}{H_m} \tag{5}$$

$$a = -N_oA\times 10^{-8}\frac{dB}{dt}$$

$$= -N_oA\mu_m\frac{H_m}{t_r}\times 10^{-8} \tag{6}$$

$$\beta = \frac{H_o}{\tan\psi} = \frac{t_rH_o}{H_m}(\text{sec}) = \frac{2\pi t_rH_o}{TH_m}\,(\text{rad}) \tag{7}$$

When the indicated substitutions are made and it is noted that under ordinary operating conditions $H_o << H_m$, the output voltage components become

$$e_o(t) = -\sum_{n\ \text{odd}}^{\infty} \frac{4N_oA\mu_mH_m}{n\pi t_r}\sin\left(\frac{2n\pi t_r}{T}\frac{H_s}{H_m}\right)\times \cos\frac{2n\pi t}{T} \tag{8}$$

$$e_o(t) = -\sum_{n\ \text{even}}^{\infty} 8N_oA\mu_mfH_o\times 10^{-8}\times \sin\left(\frac{2n\pi t_r}{T}\frac{H_s}{H_m}\right)\sin\frac{2n\pi t}{T} \tag{9}$$

Thus, with the assumption that the signal be small, equation 9 shows that the amplitudes of the even-harmonic components of the output voltage are linearly related to the signal.

In most applications, only the second-harmonic component is used as an output. This is done for two reasons:

1. Simple narrow-band amplification can be used.
2. The impedance level of the source for the second harmonic is lower than that for any higher harmonic.

For the second harmonic, equation 9 becomes

$$e_2(t) = \left[-3.2\pi N_o^2\frac{A}{l}\mu_mfI_o\times 10^{-8}\times \sin\left(4\pi f\frac{H_s}{H_m}t_r\right)\right]\sin 4\pi ft \tag{10}$$

VARIATION OF OUTPUT WITH AMPLITUDE OF EXCITATION

Equations 9 and 10 indicate that the output voltage is a function of the amplitude and rise time of the excitation as well as a function of the signal. Therefore, an optimum excitation signal is indicated. Its characteristics are found by setting

$$4\pi f\,(H_s/H_m)\,t_r = \pi/2$$

Thus,

$$\frac{H_m}{t_r} = 8H_sf = \tan\psi \tag{11}$$

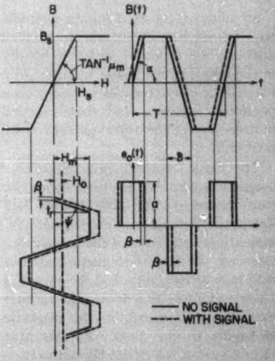

Fig. 2. Geometrical interpretation of modulator operation

Vol.
Pt.
195

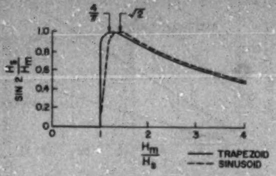

Fig. 3. Variation of output voltage with excitation amplitude

Equation 11 indicates the optimum slope of the excitation waveform in the unsaturated region.

If the excitation waveform is sinusoidal and given by

$$H(t)=H_m \sin 2\pi ft \tag{12}$$

then its initial slope is

$$\left.\frac{dH}{dt}\right|_{t=0}=2\pi fH_m \cos 2\pi ft\bigg|_{t=0}=2\pi fH_m = \tan\psi \tag{13}$$

If this value of slope is assumed to be constant in the unsaturated region, then the optimum amplitude of excitation can be found by equating equations 11 and 13.

$$\tan\psi=8H_sf=2\pi fH_m \quad \therefore \quad \frac{H_m}{H_s}=\frac{4}{\pi} \tag{14}$$

The variation of output voltage (for fixed signal) under the foregoing assumption is found by introducing equation 13 into equation 10. This yields, neglecting the minus sign,

$$\frac{E_2}{8N_oA\mu_mfH_o\times 10^{-8}}=\sin 2\frac{H_s}{H_m} \tag{15}$$

A normalized plot of this variation is shown in Fig. 3. The approximation to the magnetic characteristic accounts for the discontinuity in curve at $H_m/H_s=1$.

An analysis based directly on a sinusoidal excitation waveform[2] yields the dotted curve shown in Fig. 3.

TIME CONSTANT

The dynamic response of the modulator and its associated output filter is a function of the dynamic characteristics of both the signal-input winding and the output filter. The design of the output filter depends on the application of the modulator. Its dynamic characteristics normally can be synthesized to give any reasonable response. Since the output filter can be designed to give better dynamic response than the signal-input winding, the dynamic behavior of the modulator is determined by a single parameter; the time constant of the signal-input winding.

In so far as signal is concerned, the signal-input winding consists of an inductance L in series with the d-c winding resistance R_w. Thus the winding-time constant is given by

$$\tau=\frac{L}{R_w} \tag{16}$$

An average value of $u=\mu_a$, corresponding to the slope of the magnetization curve is used in the calculation of inductance, rather than the maximum value μ_m. The winding-time constant becomes

$$\tau=\frac{L}{R_w}=4\pi\frac{N_o^2\mu_aA}{lR_w}\times 10^{-9} \tag{17}$$

The time delay caused by hysteresis is important in a system using phase-sensitive demodulation. As a first approximation this delay is a constant depending only on the shape of the hysteresis loop and the rise time of the excitation; see Fig. 4. The amount of time delay t_d is given by

$$t_d=\frac{H_c}{\tan\psi}=\frac{H_c}{H_m}t_r \tag{18}$$

For the case of sinusoidal excitation,

$$\frac{H_m}{t_r}=2\pi fH_m \quad \therefore \quad \frac{t_d}{T}=\frac{1}{2\pi}\frac{H_c}{H_m} \tag{19}$$

POWER GAIN

It has been found experimentally that, for high-impedance excitation, a reasonable Thèvenin equivalent for the modulator as seen by the load consists of a voltage source in series with an inductor. The voltage source is equal to the open-circuit second-harmonic voltage calculated from equation 10. The reactance of the inductor is equal to the output-winding reactance evaluated at the second-harmonic frequency.

Elementary circuit theory indicates that maximum power transfer to the load occurs when R_L equals the magnitude of the source reactance. (It is assumed that $R_w<<2\omega L$.) Thus, the power delivered to R_L can be shown to be

$$P_o=3.2N_o^2\frac{A}{l}\frac{\mu_m^2}{\mu_a}I_of\times 10^{-8} \tag{20}$$

The signal power dissipated in the signal winding is

$$P_{in}=I_o^2R_w \tag{21}$$

Maximum power gain is therefore

$$G_{max}=\frac{P_o}{P_{in}}=\frac{8}{\pi}\frac{L}{R_w}\left(\frac{\mu_m}{\mu_a}\right)^2 f \tag{22}$$

If the signal winding is used for both signal and output, then the power-gain expression must be modified to include the signal power lost in R_L. The maximum power gain then will be

$$G_{max}=\frac{8}{\pi}\frac{L}{R_w+R_L}\left(\frac{\mu_m}{\mu_a}\right)^2 f \tag{23}$$

FIGURE OF MERIT

Equation 22 can be rewritten in a form that expresses a figure of merit, F_1, for modulator operation:

$$F_1=\frac{\text{Power gain}}{\text{Time constant}}=\frac{G}{\tau}=\frac{8}{\pi}\left(\frac{\mu_m}{\mu_a}\right)^2 f \tag{24}$$

While equation 24 does not account for hysteresis, core loss, or stray effects, it does indicate a fundamental design criterion for the modulator.

The factor μ_m/μ_a occurs, since the permeability upon which the output voltage depends differs from the value used to calculate nominal inductance. If experimental evidence indicates that this is actually the case, the factor μ_m/μ_a can be considered as a figure of merit for core materials. In any event, for a given core material, the modulator figure of merit, F_1, depends only on the frequency of operation.

PRACTICAL 2-CORE CURRENT-EXCITED MODULATOR

If two identical single-core modulators are arranged so that their excitation windings are in series and their output windings opposing, the combination doubles the even-harmonic output components and reduces the odd-harmonic output. The expressions governing the operation of the 2-core modulator are

$$\text{Voltage output}=e_o(t)=\left[-6.4\pi N_o^2\mu_mf\frac{A}{l}I_o\times 10^{-8}\times \sin 2\left(\frac{H_s}{H_m}\right)\right]\sin 4\pi ft \tag{25}$$

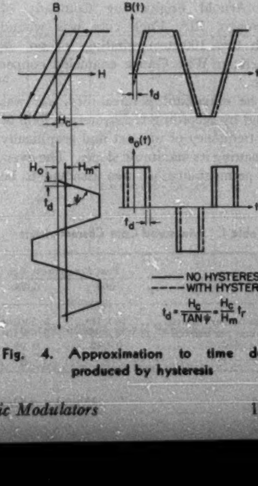

Fig. 4. Approximation to time delay produced by hysteresis

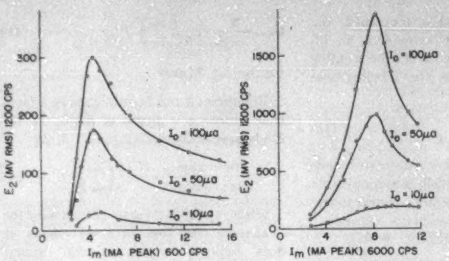

Fig. 5. Output voltage versus excitation amplitude

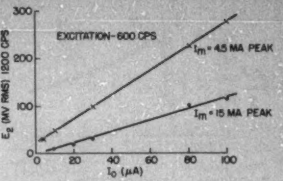

Fig. 6. Output voltage versus signal

$$\text{Time constant} = \tau = \frac{2L}{2R_w} = 4\pi\frac{N_o^2\mu_a A}{lR_w}\times10^{-9} \quad (26)$$

$$\text{Power output} = P_o = \frac{\left(\frac{2E_2}{\sqrt{2}}\right)^2}{2R_L}$$

$$= 6.4N_o^2\frac{A}{l}\frac{\mu_m^2}{\mu_a}I_o^2 f\times10^{-8} \quad (27)$$

$$\text{Power gain} = G_{\max} = \frac{P_o}{I_o^2(2R_w)} = \frac{8}{\pi}\frac{L}{R_w}\left(\frac{\mu_m}{\mu_a}\right)^2 f \quad (28)$$

$$\text{Figure of merit} = F_1 = \frac{8}{\pi}\left(\frac{\mu_m}{\mu_a}\right)^2 f \quad (29)$$

Comparison of equations 17 and 26, 23 and 28, and 24 and 29 indicates that the time constant, power gain, and figure of merit are the same for both 1-core and 2-core modulators. Thus, the only advantage of using a 2-core modulator is the suppression of odd-harmonic components.

Experimental Results

CORE PARAMETERS

The cores used in the experimental work were two 1-mil *4-79* Mo-Permalloy tape-wound toroids manufactured by the Arnold Engineering Company of Marengo, Ill.[6] Each core was wound with two 100-turn windings of no. *28* American Wire Gauge enameled copper wire.

The maximum permeability, μ_m, was found by recording the hysteresis loop at the frequency of interest and graphically measuring its maximum slope. The average permeability, μ_a, was assumed to be the slope of the normal magnetization curve. This normal curve was determined experimentally by plotting the location of the tips of the hysteresis loops as the excitation increased. A straight-line approximation was made and μ_a determined from the average slope in the unsaturated region.

These experimental techniques yield the results given in Table I.

Table I. Measured Core Characteristics

	Test Frequency, Cps	
	600	6,000
μ_m, gauss per oersted	10×10^4	5.3×10^4
μ_a, gauss per oersted	4×10^4	2.6×10^4
H_s, oersted	0.042	0.08
I_s, ma	4.0	7.6

OUTPUT-VOLTAGE CURVES

The 2-core current-excited modulator was chosen for experimental work because of its inherent rejection of odd-harmonics and its larger voltage output.

Experimental curves of output voltage versus excitation amplitude with fixed signal and output voltage versus signal with fixed excitation are shown in Figs. 5 and 6, respectively. Excitation frequencies of 600 and 6,000 cps were chosen to give reasonably large output signals and to be free of laboratory noise at the power frequency.

The curves shown in Fig. 5 can be normalized with respect to their peak amplitudes and also with respect to H_s. This is done for the case $I_o = 100$ μa (microamperes) and the results compared to the predicted theoretical behavior described by equation 15 in Fig. 7. If consideration is given to the difficulties in measuring the magnetic parameters of the cores and to the approximations made for the hysteresis loop, the expressions of the preceding "Mathematical Analysis of Operation" are in fair agreement with these experimental results.

The expression for output voltage in equation 25 becomes, upon substitution of the magnetic and physical parameters of the experimental cores,

$$e_o(t) = \left[-6.73\times10^{-5}\mu_m I_o f \sin 2\frac{H_s}{H_m}\right]\times$$

$$\sin 4\pi ft = E_2 \sin 4\pi ft \quad (30)$$

For operation at 600 cps, $\mu_m = 10\times10^4$ and $H_s = 0.042$ oersted [$I_s = 4.0$ ma (milliampere)]. Under these conditions the "transimpedance," the ratio of output voltage to input current, becomes

$$\frac{|E_2|}{I_o} = 6.73\times10^{-5}\times10\times10^4\times$$

$$600 \sin 2\left(\frac{4}{I_m}\right) = 4{,}040 \sin 2\left(\frac{4}{I_m}\right) \quad (31)$$

Equation 31 is an expression for the slope of the curve shown in Fig. 6. A comparison of these quantities is shown in Table II.

The effect of excitation frequency on transimpedance is shown in Fig. 8. At each experimental point, the amplitude of excitation current was adjusted to give maximum output voltage. Under these conditions, the transimpedance theoretically is given by

$$\frac{|E_2|}{I_o} = 6.73\times10^{-5}\mu_m f \quad (32)$$

When applying equation 32, it is important to note that μ_m is a frequency-dependent quantity. Shown in Fig. 8 are theoretical variations of transimpedance with frequency extrapolated from values of μ_m determined at 600 cps and 6,000 cps.

POWER-GAIN CURVES

Power-gain measurements, for signals of 100 μa, 30 μa, and 10 μa, were taken over five decades of resistance (R_L). The magnitude of the excitation current was adjusted to give maximum output voltage. Experimental results are indicated in Fig. 9.

The nature of the effective source impedance at the second-harmonic frequency can be found by comparing the shape of the normalized power-output curve with theoretical power-transfer curves for pure resistive and pure reactive

Table II. Transimpedance Comparison

I_m, Ma (600 Cps)	E_2/I_o (Equation 31), Ohms	E_2/I_o (Fig. 6), Ohms
4.5	3,940	3,620
15	2,040	1,830

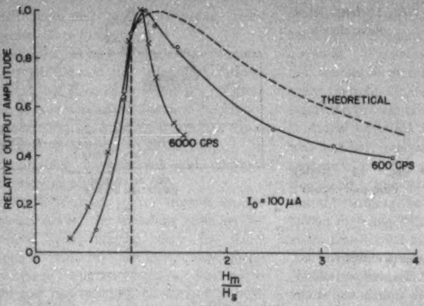

Fig. 7. Comparison of excitation amplitude curves

sources. If this comparison is made, the experimental curve is similar to the curve for reactive sources. Thus, a reasonable equivalent circuit for the modulator as seen by the load consists of a second-harmonic voltage source in series with a pure reactance.

Reference to the subsections on "Power Gain" and "Practical 2-Core Current-Excited Modulator" will indicate that maximum power gain should occur when the load resistance is equal to the output winding reactance calculated at the second-harmonic frequency. If the experimentally determined value of μ_a and the measured physical parameters are used, the inductance of the output winding is

$$L \text{ (at 600 cycles)} = \frac{N_o^2 \mu_a A}{l} \frac{4\pi}{10} \times 10^{-8}$$
$$= 168 \text{ millihenrys}$$

$$R_L \text{ (for maximum power gain)} = 4\omega L$$
$$= 2{,}540 \text{ ohms}$$

When the nominal bridge-measured value of $L = 75$ millihenrys is used,

$$R_L \text{ (for maximum power gain)} = 1{,}150 \text{ ohms}$$

Fig. 9 indicates a value of $R_L = 1{,}500$ ohms, which is bracketed by the calculated values.

The value of maximum power gain is given by equation 28. When the measured values of the parameters are used, the theoretical power gain becomes

$G_{\max} = 2{,}220$ (using calculated value of L)

$G_{\max} = 990$ (using nominal measured value of L)

Fig. 9 indicates a value of $G_{\max} = 1{,}400$, which is bracketed by the calculated values.

Conclusions and Design Considerations

Several aspects of the mathematical analysis of operation developed in a previous section have been verified by the work shown in the section on "Experimental Results." The correlation between the analysis and the experiment is sufficiently high to allow the analysis to be used as a basis for design of second-harmonic magnetic modulators. Presented in the following are conclusions and design criteria based on the work of these sections and also the work of other experimenters in the field.[3,7,8]

Choice of Modulator Configuration

Perhaps the simplest configuration consists of a single-core wound with a sufficient number of windings to supply excitation, signal, and output requirements. The major disadvantage of such a configuration is the presence of large odd-harmonic components in the output winding. These components are usually much larger than the desired second-harmonic output signal and, unless selective circuits are used, there exists the possibility of overloading the stage following the modulator, and generating spurious signals.

A much better configuration consists of two cores arranged so that the odd-harmonic components in each output winding cancel each other and hence do not appear in the output. The degree of odd-harmonic suppression depends on how well the magnetic characteristics of the two cores are matched. Normally two physically similar cores will be sufficiently well matched to give on the order of a 10-to-1 suppression of odd harmonics. This can be improved by selecting cores or by adjusting the windings on each core to give the effect of matched cores. Differences in the width of the hysteresis loop can be minimized by altering the number of excitation turns in one or the other of the cores. Similarly, differences in maximum flux density can be minimized by altering output-winding turns.

Choice of Excitation

A most important consideration in the choice of an excitation source is that it be able to supply sufficient magnetomotive force to saturate the core. In addition, the waveform of the excitation must be free from the harmonic component used as the output. To insure this, adequate filtering in the excitation circuit is necessary. Modulator transimpedance is a function of excitation amplitude; thus amplitude stability is important to prevent changes in gain.

Choice of excitation frequency depends on many factors. Output signal frequency and amplitude are directly dependent on excitation frequency; hence equipment following the modulator may dictate the choice. The most important factors to be considered are given in the following.

Factors favoring low excitation frequency:

1. Economy of excitation power.
2. Small core loss, and hence less heating.
3. Low impedance levels.
4. Freedom from winding resonances.

Factors favoring high excitation frequency:

1. Large gain.
2. Fast time response thereby accommodating wider bandwidths of input signal.

It appears that high-frequency operation is advantageous because of the large gains and speed of response available. This must be tempered with the fact that desirable magnetic properties are unfavorably altered with increases in frequency. Also, since frequencies are ultimately reached where excitation power increases at least as the square of frequency, temperature rise may well be the limiting factor.

Choice of Output

A system that uses the sum of all even-harmonic components would utilize the maximum energy available as output. Such a system would require wide-band amplification and demodulation schemes.

Single-frequency output eliminates the foregoing difficulties. Experimentally, it has been found that the fourth- and sixth-harmonic amplitudes are smaller than the second-harmonic amplitude for a given signal. This, coupled with the fact that the second-harmonic impedance is lower than that of the higher harmonics, tends to indicate that the second-harmonic component is most desirable as the output frequency.

Choice of Core Material

Materials having high maximum permeability are best suited for use in magnetic modulators. Low core loss is important since it is desirable to operate the core at high frequencies without excessive heating. Thus a figure of merit for core materials operated at the upper end of their useful range can be defined as $\mu_m f_c$, where f_c is the frequency at which the core loss becomes appreciable.

Reference to the subsection, "Figure of Merit," indicates that an additional figure of merit for core materials might be μ_m/μ_a. Lack of time, however, has prevented experimental verification of its validity.

Core Shape and Size

Since very high permeabilities are sought, air gaps must be eliminated. This suggests the use of toroidal cores. In order to reduce core losses, lamination (or tape) thickness should be minimized, One-mil tape is common, 1/8-mil tape is available, and thinner tapes are in prospect. If a fixed volume is available for windings, both power output and time response depend directly on the ratio of core cross-sectional area to mean core length. Thus, the core size will depend on a compromise between the conflicting factors.

Windings

The excitation winding should take up as little of the available winding space as possible. Its wire size and number of turns will depend on the magnetomotive force required to saturate the core and the internal impedance of the excitation source. The winding should be distributed over the core so that the flux density is uniform across the area.

Separate windings for signal and output result in isolation between signal and output circuits but reduce sensitivity. Separate windings also allow impedance matching between signal source and modulator and between modulator and load. The main advantage of a single winding used for both signal and output is the increase in sensitivity.

Circuits for Realizing Maximum Power Gains

The use of a single winding for both signal and output is not always compatible with impedance matching for maximum power transfer. Three techniques present themselves as solutions to this problem: (1) separate windings for signal and output; (2) the use of a transformer; and (3) "push-pull" arrangements. The choice among these methods depends on the impedances of the sources to be matched, and the relative frequencies of the signal and output. The matching problem is further complicated because the modulated output signal is always present across the same terminals to which the signal is applied.

The matching problem is fairly easy in the case of a high-impedance signal source and a load of somewhat lower impedance. Fig. 10(A) indicates one method. A blocking capacitor for signal frequencies may be placed in series with R_L if signal and output frequencies are well separated and if winding resonances do not occur.

In Figs. 10 and 11 single-core modulators are shown for simplicity. However, the circuits are equally effective for 2-core modulators which (as shown under "Practical 2-Core Current-Excited Modulator") offer the advantage of suppressing fundamental and odd-harmonic components.

As the signal source impedance becomes lower, the matching problem becomes more difficult, since the signal source tends to short-circuit the output winding. The use of a series load resistance is not effective because of the undesirable loss of signal power in R_L. The circuit of Fig. 10(B) employs a transformer, which is used to present low-impedance to signal frequencies and high impedance at the output frequency. The major difficulty of this circuit lies in the realization that the transformer itself may act as a modulator and introduce output components bearing no relation to the input signal.

The push-pull circuit shown in Fig. 11(A) eliminates the nonlinear difficulties of Fig. 10(B) by virtue of the inherent even-harmonic suppression of such a system. It is necessary that the excitation sources be 90 degrees out of phase in order that the circuit act in a push-pull manner at the second-harmonic frequency. It should be noted that two reasonably well-matched magnetic modulators are necessary for this circuit to operate effectively. In addition, the dynamic characteristics of the center-tapped transformer must meet the same requirements as the transformer in Fig. 10(B).

A modified push-pull circuit which eliminates the need for an external transformer is shown in Fig. 11(B). Here the cores themselves act as the center-tapped transformer. Output is taken from a third set of windings on the core. Since these windings are isolated from the signal input windings the output-winding impedance does not affect the signal power delivered. By adjusting turns and wire size, the output-winding impedance can be independently matched to the load R_L. This circuit still requires that the excitation sources be 90 degrees out of phase.

On Feedback in Magnetic Amplifiers

Part I—Single Feedbacks

L. A. FINZI
MEMBER AIEE

J. J. SUOZZI
ASSOCIATE MEMBER AIEE

FEEDBACK TECHNIQUES are receiving considerable attention in the magnetic-amplifier field and many ways have been suggested in which the output quantity can be chosen and employed to modify the controlling action of the signal. This paper examines and compares a variety of feedback configurations that are associated with 2-core full-wave self-saturating amplifiers. A companion paper, Part II, extends the study to combined feedbacks, as used in "self-balancing" amplifiers.[1]

Expressions are presented for input and output impedances, and gains in the steady state with the loading effects of the components of the feedback loop taken into account where necessary. The transient and frequency response are treated, extending familiar "slow-transient" approaches to the various circuitries and showing the influence of coupled feedback circuits upon the gain-bandwidth product. A difference-equation approach is used subsequently and "modular" time constants are derived which befit the jump-function character of the variables.

The present study is limited to resistive loads and feedback networks without frequency-dependent elements; the operation over the "negative branch" of the transfer characteristic is not considered.

I. Terminology: Algebraic Conventions

Since a unified language is lacking in the literature, definitions are given as to the output quantity chosen to perform feedback and the manner in which this quantity is used. The terms "load-voltage feedback," "load-current feedback" and "gate-winding current feedback," with or without potentiometers and shunts, refer to the quantity chosen and are self-explanatory.

"Electric" (or galvanic) feedback exists when the output quantity or some fraction thereof is applied to the signal circuit. It may act in series with the signal source ("series" electric feedback), or across the terminals of the signal winding ("shunt" electric feedback).

"Magnetic" or mmf (magnetomotive force) feedback occurs when the output quantity acts upon the resetting core through windings other than the signal winding. A variety of practical situations are covered by this definition.

Mmf of windings on any core are positive when in the direction of positive fluxes, and positive currents give positive

Paper 58-1231, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted June 26, 1958; made available for printing August 26, 1958.

L. A. Finzi is with Carnegie Institute of Technology, Pittsburgh, Pa., and J. J. Suozzi is with the Bell Telephone Laboratories, Inc., Whippany, N. J.

This work was performed at the Carnegie Institute of Technology under the sponsorship of the Minneapolis-Honeywell Regulator Company, Brown Instruments Division, Philadelphia, Pa. Portions of the paper are abstracted from a dissertation by J. J. Suozzi, submitted to the Carnegie Institute of Technology in partial fulfillment of the requirements for the degree of Doctor of Philosophy. Useful suggestions by Prof. A. B. Heins and A. G. Milnes of Carnegie Institute of Technology and by G. F. Pittman, Jr., of the Westinghouse Electric Corporation are gratefully acknowledged.

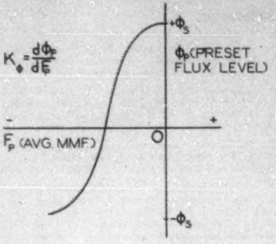

Fig. 1. Core-control curve

mmf when entering the dot terminal of a winding. The "positive branch" of a transfer characteristic covers the common type of operation in which the flux of the gating core rises from the preset flux level, ϕ_p, to saturation $+\phi_s$, while the flux of the other core during the same half-cycle resets from positive saturation. The amount of reset, $\phi_s-\phi_p$, increases for algebraic decreases of the half-cyclic average mmf F_p, of all the currents acting upon the resetting core. Hence larger outputs result from algebraic increases of signal, regardless of bias or feedback. Positive feedbacks act in the same direction as positive increases of signal.

Given a pair of cores with gate windings N_g, and signal windings N_c, any particular type of amplifier circuitry could be chosen as the starting point for further modifications by feedback. At earlier times, the simple saturable reactor has been used for this. In the following the self-saturating amplifier (bridge, center tap, or doubler) is preferred; more specifically the bridge circuit is taken as the basis of reference, although the center-tap circuit would have been equally suitable. Systems derived from the doubler, or from an equivalent saturable reactor with "100% extrinsic feedback," are more vulnerable to unblocking effects, which limit the validity of the treatment.

II. The Control Curve

It is assumed that the initial flux ϕ_p, of the gating core can be related simply to the half-cyclic average F_p, of all mmf that acted upon it in the preceding reset half-cycled by means of a "core-control curve" $\phi_p=f(F_p)$; see Fig. 1. It is also assumed that the resetting process initiates when the alternating voltage at the gate terminals passes through zero.

The latter assumption is true if the signal voltage is unidirectional and has the same wave form and phase before rectification as the gate voltage. It remains acceptable practically in more general situations (e.g., sinusoidal gate voltages and d-c signals) for self-saturating amplifiers even when comparatively large negative feedbacks are introduced. The assumed uniqueness of a control curve is more questionable. The general understanding of dynamic core behavior, incomplete as it may be, leads one to doubt that different half-cyclic processes arriving at a certain ϕ_p with different instantaneous rates should result ultimately in a common value of the half-cyclic average F_p, but the acceptance of a core-control curve remains the best available for the purposes at hand and is preferable by far to arbitrary postulations of idealized cores. Core-control curves obtained from transfer characteristics measured at the pertinent gate voltage and frequency, preferably with low control circuit constraint, proved quite adequate in the experimentation. Departures from analytical predictions arose rather for cases in which the rectifiers blocked or unblocked at improper times.

III. Steady-State Gains, Input and Output Resistances

III-1. DEFINITIONS

Capital letters indicate half-cyclic average values. Instantaneous values are indicated by lower-case letters.

E_g = a-c supply voltage. (For $e_g=E_{gm}\sin\omega t$, $E_g=(2/\pi)\,E_{gm}$; not $E_{gm}/\sqrt{2}$)
E = gross output voltage (i.e., the part of the supply voltage not absorbed by the half-cyclic swing of fluxes)
V_L = voltage across the load resistor R_L. (I_L = load current $=V_L/R_L$)
E_c = applied signal voltage (not necessarily a pure direct current)
I_i = input current
I_c = current *in the signal windings N_c. ($I_c=I_i$ except for circuits with shunt-electric feedback)
R_i = input resistance $=dE_c/dI_i$
$K_E=dE/dE_c$ = gross output-voltage gain, static
$K_{EN}=K_EN_c/N_g$ = gross output-voltage gain per turn, static
$K_V=dV_L/dE_c$ = net output-voltage gain (load-voltage gain), static
$K_A=dI_L/dI_i$ = current gain, static
$K_{VA}=K_V\times K_A$ = load volt-ampere gain, static
$K_{EA}=K_E\times K_A$ = gross volt-ampere gain, static

III-2. BASIC SELF-SATURATING CIRCUITS

The familiar bridge circuit and also the center-tap and doubler circuits are presented in Appendix I, mainly to explain certain definitions of symbols. The resistance of a gate winding is indicated by r_g, and r_{gr} is the sum of r_g and of the linearized forward resistances $r\gamma$ (and

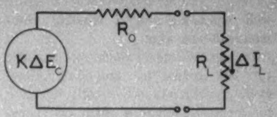

Fig. 2. Thevenin equivalent of output circuit

also $r\sigma$ for the bridge) of the conducting diodes in the gating path. Rectifier leakage is assumed negligible and may be considered separately as a particular kind of negative magnetic feedback; see section III-4(d). The differential equation of the gating circuit during positive half-cycles, with $\dot\phi=d\phi/dt$ is

$$e_g=N_g\dot\phi_1+(R_L+r_{gr})i_{g1}=N_g\dot\phi_1+R_gi_L \qquad (1)$$

If steady state with constant signal prevails, a half-cyclic time integration yields

$$E_g=2fN_g(\phi_s-\phi_p)+R_gI_L$$
$$=2fN_g(\phi_s-\phi_p)+E \qquad (2)$$

(To include cases of "subnormal" excitation, i.e., $E_g<4fN_g\phi_s$, the restriction $2fN_g(\phi_s-\phi_p)<E_g$ is added to specify the range of ϕ_p for which equation 2 is valid. In other words, the initial ϕ_p must be such that $+\phi_s$ is reached within the half-cycle.)

The control circuit resistance R_c is the sum of the resistances $2r_c$, of the control winding and, in general, of an additional resistor R_k in series. With $R_c=R_k+2r_c$, the differential equation of the signal circuit is

$$e_c=R_ci_c+N_c(\dot\phi_1+\dot\phi_2) \qquad (3)$$

whence

$$E_c=R_cI_c \qquad (4)$$

if the steady state is considered. The gross output-voltage gain of the basic amplifiers (marked by an asterisk in the following) is

$$K_E{}^*=\frac{dE}{dE_c}=\frac{dE}{d\phi_p}\,\frac{d\phi_p}{dF_p}\,\frac{dF_p}{dE_c}=2fN_gK_\phi\frac{N_c}{R_c} \qquad (5)$$

where $K_\phi=d\phi_p/dF_p$ is the slope of the core-control curve, Fig. 1, at any ϕ_p. The corresponding gross output-voltage gain per turn is

$$K_{EN}{}^*=K_E{}^*\frac{N_c}{N_g}=2fK_\phi\frac{N_c{}^2}{R_c} \qquad (6)$$

III-3. MODIFICATIONS BY FEEDBACK: PROCEDURE AND PRESENTATION OF RESULTS

Modifications of the original bridge-amplifier by feedbacks of various kinds are analyzed from the equations of the network in terms of half-cyclic average voltages and currents, and from the mmf of reset F_p, as the sum of the contributions given by the various windings on the core; the algebra is straightforward and does not need to be given in detail here.[2] Care has been taken to preserve loading terms (i.e., terms containing shunt and potentiometer resistances, etc.) in the expressions obtained. Loading effects of the feedback networks of magnetic amplifiers are less likely to be negligible than in similar configurations with electronic amplifiers. (Certain simplifications of some final expressions of the analysis are stated at pertinent places in the tabulation of results.)

The quantities given in Appendixes I through III are the gross voltage gain, K_E; the input resistance, R_i; the output resistance R_o; and the generator gain $\mathcal{K}$, of the Thevenin equivalent of the output circuit of the amplifier system; see Fig. 2. For all cases, the load voltage gain K_V and the current gain K_A are given by

$$K_V = \mathcal{K}R_L/(R_L+R_o)$$

and

$$K_A = \mathcal{K}R_i/(R_L+R_o)$$

The winding polarities of the schematic diagrams and the upper algebraic signs of the expressions apply for negative feedback action; the lower algebraic signs refer to positive feedback action. N_b and R_b are turns and resistances of bias circuits, not shown on the schematics. (Other quantities presented in the tables refer to the study of transient and frequency response; their meaning is explained in section IV.)

The various classes of magnetic and electric feedback considered are described briefly in the following.

III-4. MAGNETIC FEEDBACKS

(a). *Load-Current Feedback into Separate N_f-Coils, Appendix II(A):* The unidirectional load current, or a part thereof, derived from a shunt r_s, in series with the load R_L, is fed into two N_f-coils, thus providing an additional negative (or positive) mmf.

(b). *Load-Voltage Feedback into Separate N_f-Coils, Appendix II(B):* Here the N_f-coils are supplied from the unidirectional load voltage across the load or a part thereof, obtained from a potentiometer R_1+R_2 across the load.

(c). *Gate-Winding-Current Feedback in Cross-Connected Feedback Windings, Appendix II(C):* Here, the feedback turns N_f on one core are connected in series with the gate winding of the opposite core, so that the gate current of the firing core gives a contribution (negative or positive), to the mmf of the resetting core.

(d). *Negative Feedback Action of Shunted Gate Rectifiers, Appendix II(D), (E), and (F):* The self-saturating rectifiers γ of the bridge, center tap, and doubler circuits, are shunted by resistors R_{sh}, allowing a current to flow in the gate winding of the resetting core with a negative contribution to the mmf of the resetting core. The reverse rectifier voltages are different in the three basic circuits and accordingly each circuit is treated separately. For bridge and center-tap circuits, the feedback resembles a negative magnetic load-voltage feedback of item (b). For the doubler, the feedback is more nearly a negative current magnetic feedback such as in item (a). The shunting of rectifiers with adequately high R_{sh} resistors offers a simple way to reduce the voltage gain, if so desired. The adverse effects of rectifier leakage on voltage gains are also expressed by this treatment if the "reverse resistance" of the leaky rectifier is approximated by the linearized constant value R_{sh}.

(e). *The Positive Feedback Action of Unblocking Rectifiers.* The treatment given in this paper assumes that no unblocking of the rectifiers occurs, but a passing remark may be appropriate. Phenomena that may conceivably cause the rectifier of the resetting core to conduct in its forward direction result in a positive contribution to the average mmf of the resetting core. This is a sort of spurious positive feedback, opposite in its essence to the negative feedback of rectifier leakage. If the amplifier in the absence of unblocking has a rather high gain K_E to start with, any agent that induces unblocking (i.e., unusual constraints in the signal crcuit or, in addition, some inductance in the gate circuit) may result in infinite or negative gains over some range of the characteristic, and thus in unwelcome instabilities.

(f). *The Simple SR (Saturable Reactor).* The "inherent" negative feedback of the SR is a type of negative magnetic feedback. In the series-connected SR, the output current flowing in the gate winding of the resetting core gives a negative contribution to the mmf F_p. The parallel connected SR is a limiting case of the doubler with shunted gate rectifiers.

III-5. ELECTRIC FEEDBACKS

(a). *Series Load-Current Feedback, Appendix III(A):* The voltage drop across a shunt resistor r_s, in series with the load R_L, is injected into the signal circuit in series with the signal source.

(b). *Series Load-Voltage Feedback, Appendix III(B):* The voltage obtained from a potentiometer across the load is injected into the signal circuit in series with the signal source. Here (and in subsequent figures in the appendixes) certain approximations, as stated, have been introduced in view of the usual orders of magnitude of certain terms in the relationship.

(c). *Shunt Load-Current Feedback, Appendix III(C):* The voltage drop as in item (a) is applied across the terminals of the signal winding through a resistance R_a. The resistance $2r_c$ of the signal windings is expressed explicitly in the analysis, i.e., $(R_c = R_k + 2r_c)$.

(d). *Shunt Load-Voltage Feedback, Appendix III(D):* The potentiometer voltage is applied across the terminals of the signal winding through a resistance R_a.

IV. Transient and Frequency Response

IV-1. BASIC AMPLIFIER AND ITS DIFFERENCE EQUATIONS

If the amplifier processes do not repeat half-cycle by half-cycle, the half-cyclic time integration of equation 1 performed from

$$t = \frac{(n-1)\pi}{\omega} \text{ to } t = \frac{n\pi}{\omega}$$

with n = a positive integer, yields more generally

$$E_{g(n)} = 2fN_g(\phi_s - \phi_{p(n-1)}) + E_{(n)} \qquad (7)$$

Equation 7 relates the gross output average voltage $E_{(n)}$ of the nth half-cycle to the corresponding half-cyclic average gate voltage $E_{g(n)}$, and to the preset flux level $\phi_{p(n-1)}$, i.e., to the flux level reached by the resetting core at end of the previous half-cycle.

Equation 3 integrated over the nth half-cycle yields

$$E_{c(n)} = R_cI_{c(n)} + 2fN_c(\phi_{p(n)} - \phi_{p(n-1)}) \qquad (8)$$

Equation 8 relates the half-cyclic average signal voltage and current $E_{c(n)}$ and $I_{c(n)}$ and the difference of the preset flux levels $\phi_{p(n)}$ and $\phi_{p(n-1)}$ attained at the end of the nth and $n-1$th half-cycle respectively.

In section II, the flux level ϕ_p, attained by a core at the end of its half-cycle of reset, has been related to the half-cyclic average F_p of all the mmf that acted upon the core during that half-cycle by means of a given core control curve $\phi_p = f(F_p)$. No additional inaccuracies are introduced if the same curve is used in the transient analysis to relate $\phi_{p(n)}$ to $F_{p(n)}$ at least as long as the assumption of negligible unblocking holds in the transient condition.

IV-2. THE USE OF APPROXIMATE DIFFERENTIAL EQUATIONS

A time-honored approach is that in which equation 8 is converted into an approximate differential equation:

$$E_c = R_c I_c + N_c d\phi_p/dt \tag{9}$$

where the discrete values of equation 8 are substituted by continuous variables.

In the basic amplifier without bias windings $F_p = N_c I_c$, and thus equation 9 is converted into the approximate differential equation

$$E_c(t) = \frac{R_c}{N_c} F_{p(t)} + N_c \frac{d\phi_{p(t)}}{dt}$$
$$= \frac{R_c}{N_c} F_{p(t)} + N_c K_\phi \frac{dF_{p(t)}}{dt} \tag{10}$$

If K_ϕ is a constant (i.e., if the voltage gain $K_E{}^* = 2fN_g K_\psi N_c/R_c$ does not vary significantly over the range of outputs of interest), the transient of $F_{p(t)}$, (and thus of $\phi_{p(t)}$), is characterized by a simple time constant

$$\tau_a = K_\phi \frac{N_c{}^2}{R_c} = \frac{1}{2f} K_E{}^* \frac{N_c}{N_g} = \frac{1}{2f} K_{EN}{}^* \text{ seconds} \tag{11}$$

(If $K_E{}^*$ varies significantly over the range, graphical integrations of equation 9 remain possible.)

The transient output $E_{(t)}$ is obtained then, also as a continuous time function using $\phi_{p(t)}$ in equation 2. This approach is adequate for transients that are long compared to the half-cycle of the gate frequency. The concept of a half-cycle "transportation lag" has been suggested to account for the fact that the output of one half-cycle depends on the preset flux level found at the end of the previous half-cycle. However, the substitution of an approximate continuous differential equation for the original equation 8 is, in itself, a source of error of the same order of magnitude as that attempted correction. For fast transients, where this matter becomes significant, a consistent solution of the difference equations is preferable; see section IV-5.

As is generally known, if additional circuits are coupled directly to the control circuit, such as a bias circuit with N_b turns per core and total resistance R_b, equation 10 modifies into

$$\tau_a = \frac{1}{2f} K_{EN}{}^* \left(1 + \frac{R_c}{R_b} \frac{N_b{}^2}{N_c{}^2}\right) \text{ seconds} \tag{12}$$

Here, τ_a is still the time constant of the transient of both $F_{p(t)}$ and $\phi_{p(t)}$.

IV-3. EXTENSIONS OF APPROXIMATE APPROACH TO AMPLIFIERS WITH FEEDBACK

One may extend the slow-transient approach to amplifiers with magnetic or electric feedbacks, writing the instantaneous differential equations of the various loops, converting them into difference equations, and then approximating their discrete variables with continuous time functions. The procedure is illustrated in two examples.

For magnetic load-current feedback, Appendix II(A), the control circuit equation remains equation 9. Then $I_{c(t)}$ is expressed in terms of $F_{p(t)}$ as

$$F_{p(t)} = N_c I_{c(t)} \mp N_f I_{f(t)} \mp N_b I_{b(t)} \tag{13}$$

where the upper signs apply for negative feedback (and for negative bias respectively). The voltage equation of the bias circuit, in approximate continuous form is

$$E_{b(t)} = R_b I_{b(t)} \mp N_b \frac{d\phi_{p(t)}}{dt} \tag{14}$$

The voltage equation of the gate and feedback circuit in difference form is

$$E_{g(n)} = 2fN_g(\phi_s - \phi_{p(n-1)}) + \frac{R_f R_g{}'}{r_s} I_{f(n)} \mp$$
$$2fN_f \frac{R_g}{r_s} (\phi_{(pn)} - \phi_{p(n-1)}) \tag{15}$$

from which is obtained the approximate differential equation

$$E_{g(t)} = 2fN_g(\phi_s - \phi_{p(t)}) + \frac{R_f R_g{}'}{r_s} I_{f(t)} \mp$$
$$\frac{R_g}{r_s} N_f \frac{d\phi_{p(t)}}{dt} \tag{16}$$

$F_{p(t)}$ is expressed by $F_{p(t)} = (\phi_{p(t)} - \phi_K)/K_\phi$ if the control curve is linearized over the range of interest, where ϕ_K is the intercept of the straight line with the ϕ_p axis and $\phi_{p(t)}$ is expressed as a function of time by the differential equation

$$E_c \mp E_b \frac{N_b}{N_c} \frac{R_c}{R_b} \mp \beta(E_g - 2fN_g\phi_s)$$
$$= (\phi_{p(t)} - \phi_K)\left(\frac{1 \pm \beta K_E{}^*}{K_\phi N_c/R_c}\right) +$$
$$N_c\left(1 + \frac{N_f{}^2 R_c R_g}{N_c{}^2 R_f R_g{}'} + \frac{N_b{}^2 R_c}{N_c{}^2 R_b}\right)\frac{d\phi_{p(t)}}{dt} \tag{17}$$

Hence, for constant E_c, E_b, and E_g, the transient of $\phi_{p(t)}$ is given by

$$\phi_{p(t)} - \phi_K$$
$$= \left[\frac{E_c \mp E_b \frac{N_b}{R_b} \frac{R_c}{N_c} \mp \beta(E_g - 2fN_g\phi_s)}{1 \pm \beta K_E{}^*}\right]$$
$$K_\phi N_c/R_c \left(1 - \epsilon^{-\frac{t}{\tau_a}}\right) \tag{18}$$

where

$$\tau_a = \frac{1}{2f} K_{EN}\left(1 + \frac{N_f{}^2 R_c R_g}{N_c{}^2 R_f R_g{}'} + \frac{N_b{}^2 R_c}{N_c{}^2 R_b}\right) \tag{19}$$

with the symbols defined in Appendix II(A). It is seen that the feedback loop introduces a coupling term similar to that of a bias circuit. Writing the voltage equation of the feedback loop yields

$$r_s I_{L(t)} = (R_f + r_s) I_{f(t)} \mp N_f d\phi_{p(t)}/dt$$

and, substituting in equation 16, the load current $I_{L(t)}$ is obtained as

$$I_{L(t)} = \left(\frac{r_s + R_f}{R_f R_g{}'}\right)(E_g - 2fN_g(\phi_s - \phi_{p(t)})) \pm$$
$$\frac{N_f}{R_g{}' R_f}\left(R_g - \frac{R_g{}' R_f}{r_s}\right)\frac{d\phi_{p(t)}}{dt} \tag{20}$$

According to this approach, $I_{L(t)}$ is the sum of two exponential terms, both with the same time constant τ_a; the second right-hand term expresses the fact that transient voltages are induced in the feedback loop associated with the output. The ambiguous concept of a continuous $I_{L(t)}$ does not warrant pursuing this point further.

For series electric load-current feedback, the difference equation of the control circuit is

$$E_{c(n)} = (R_c + r_s) I_{c(n)} \pm r_s I_{L(n)} +$$
$$2fN_c(\phi_{p(n)} - \phi_{p(n-1)}) \tag{21}$$

The difference equation of the gate circuit is

$$E_{g(n)} = R_g I_{L(n)} \pm r_s I_{c(n)} + 2fN_g(\phi_s - \phi_{p(n-1)}) \tag{22}$$

Equations 21 and 22 for E_c constant become in approximate form

$$E_c = (R_c + r_s) I_{c(t)} \pm r_s I_{L(t)} + N_c d\phi_{p(t)}/dt \tag{23}$$

$$E_{g(t)} = R_g I_{L(t)} + 2fN_g(\phi_s - \phi_{p(t)}) \pm r_s I_{c(t)} \tag{24}$$

With $F_{p(t)} = N_c I_{c(t)} \mp N_b I_{b(t)}$ and with constant E_g, the general equation for the control circuit becomes

$$E_c \mp E_b \frac{N_b}{N_c} \frac{R_c}{R_b} (1 + \nu) \mp \beta(E_g - 2fN_g\phi_s)$$
$$= (\phi_{p(t)} - \phi_K)\left(\frac{1 + \nu \pm \beta K_E{}^*}{K_\phi N_c/R_c}\right) +$$
$$N_c\left(1 + \frac{N_b{}^2}{N_c{}^2} \frac{R_c(1 + \nu)}{R_b}\right)\frac{d\phi_{p(t)}}{dt} \tag{25}$$

This approximate differential equation describes the transient of $\phi_{p(t)}$. The time constant τ_a, is given in Appendix III(A). The output current $I_{L(t)}$ in this case is affected by the control current through the galvanic coupling, but once more its time constant is τ_a.

All other types of feedback may be treated in the same manner. The corresponding expression of τ_a are presented in the Appendixes. The effect of coupled loops arising from the introduction of magnetic (or shunt electric) feedbacks is to reduce the voltage gain-bandwidth product. The concept that the gain-bandwidth product is invariant with feedback is therefore only a first-order approximation.

Equations 10, 17, and 25 describe the transient of $\phi_{p(t)}$ arising conceivably not only from changes of the control voltage E_c, but also from changes of any other quantity that appears in these equations. Note that the time constant of the transient is defined by the values of the circuit parameters which exist after the change while the initial value of ϕ_p to be used in equations 10, 17, and 25 is that prevailing before the change.

IV-4. Limitations of Approximate Approach

If finer issues of "half-cyclic lags" and associated phase shifts are important, the approximate treatment described in the foregoing is not adequate. The transition from equation 8 to equation 9 loses the resolution required, and a direct solution of the original difference equations is necessary. The techniques of solving are similar to those of common differential equations of the same order. A disadvantage is seen, at first, because the solution is in the form of a geometric progression rather than an exponential; however, the desirable familiar concept of time constants can be preserved as shown originally by Kikuchi[3] for the basic amplifier. A comprehensive treatment is presented in the following. Again attention is focused on ϕ_p(i.e., on $\phi_{p(n)}$) as the key variable.

IV-5. Modular Differential Equation of Basic Amplifier

(a). *Response to a Step of D-C Control Voltage:* To simplify the writing, it is understood in the following that all variables are increments from some initial steady-state value. Hence the flux level $\phi_{p(n)}$ established at the end of the nth half-cycle is related to the average mmf, $F_{p(n)}$, that acted upon the resetting core during that half-cycle simply by $\phi_{p(n)}=K_\phi F_{p(n)}$, assuming K_ϕ is constant over the range of interest.

In the basic amplifier without bias circuits $F_{p(n)}=N_cI_{c(n)}$, and thus equation 8 becomes

$$E_{c(n)}=\frac{R_c}{K_\phi N_c}\,\phi_{p(n)}+2fN_c(\phi_{p(n)}-\phi_{p(n-1)}) \tag{26}$$

This difference equation is linear with constant coefficients over the range. For a step of d-c signal voltage E_c, at the beginning of the first half-cycle, equation 26 can be rewritten as

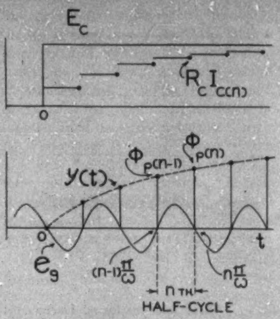

Fig. 3. Transient of preset flux $\phi_{p(n)}$ and control current $I_{c(n)}$

$$\phi_{p(n)}-\alpha\phi_{p(n-1)}=\zeta E_c \tag{27}$$

where $\zeta=\dfrac{K\phi\dfrac{N_c}{R_c}}{1+K_{EN}}$ and

$\alpha=K_{EN}{}^*/1+K_{EN}{}^*<1$ and its solution is

$$\phi_{p(n)}=\zeta\,\frac{E_c(1-\alpha^n)}{1-\alpha}=E_cK_\phi N_c/R_c(1-\alpha^n) \tag{28}$$

Fig. 3 shows the transient processes as described by the solution of the difference equation. The concept of a time constant is preserved by writing an auxiliary linear differential equation

$$\frac{dy}{dt}+ay=b \tag{29}$$

and prescribing that its solution will satisfy the condition

$$y(t)=\phi_{p(n)} \text{ at } t=\frac{n\pi}{\omega},\ n=0,\ 1,\ 2,\ 3\ \ldots$$

(In other words, the solution of the modular differential equation 29 is a continuous function, shown by the line which passes through the points expressing the discrete values of ϕ_p in Fig. 3.) The condition is met if

$$a=\frac{\omega}{\pi}\ \ln\frac{1}{\alpha};\quad b=\left(\frac{\omega}{\pi}\ \ln\frac{1}{\alpha}\right)\frac{\zeta E_c}{1-\alpha} \tag{30}$$

The function, $y(t)$ is characterized by a time constant

$$\tau_y=\frac{1}{a}=\frac{\pi}{\omega}\ \frac{1}{\ln 1/\alpha} \tag{31}$$

where $0<\alpha<1$

and the usefulness of this modular time constant to express amplifier transient is evident from Fig. 3.

Since $\alpha=K_{EN}{}^*/(1+K_{EN}{}^*)$, it follows that

$$\ln\frac{1}{\alpha}=\ln\left(\frac{1+K_{EN}{}^*}{K_{EN}{}^*}\right)=2\left[\frac{1}{(2K_{EN}{}^*+1)}+\frac{1}{3}\left(\frac{1}{2K_{EN}{}^*+1}\right)^3+\frac{1}{5}\left(\frac{1}{2K_{EN}{}^*+1}\right)^5\cdots\right]$$

$$\approx 2\left(\frac{1}{2K_{EN}{}^*+1}\right)$$

with an error of less than 4% if $K_{EN}{}^*\geq 1$. Hence

$$\tau_y\approx\frac{\pi}{\omega}\left(K_{EN}{}^*+\frac{1}{2}\right)\text{ seconds} \tag{32}$$

This expression is now compared with the approximate time constant of equation 11, and it is seen that

$$\tau_y\approx\tau_a+\frac{1}{2}\,\frac{\pi}{\omega}\text{ (seconds)} \tag{33}$$

The readjustments of ϕ_p in this approach are slower than are predicted by the approximate time constant τ_a; the two approaches are essentially equivalent if $K_{EN}{}^*$ is large, as should be expected, because then the transient is slow.[3]

In addition, a half-cyclic transportation lag remains inherent to the half-cyclic average output current of the basic amplifier because $I_{L(n)}$ is determined solely by $\phi_{p(n-1)}$. Actually, in questions of fast response, the waveform of the instantaneous i_L may be of significant interest; the angle of firing, however, is easily obtained from the half-cyclic average values.

If a bias circuit is coupled, it can be shown that τ_y is still given by equation 33. In this case, however, τ_a is given by equation 12.

(b). *Sinusoidal Response:* Consider a signal, $e_c=E_{c(\max)}\sin\Omega t$, applied to the original bridge circuit (suitably biased from a d-c source) at the beginning of a half-cycle of the gate voltage. The angular frequency Ω of the signal is smaller than the carrier frequency ω. The values of ϕ_p, as increments from the value due to the bias, are obtained from the difference equation

$$\phi_{p(n)}-\alpha\phi_{p(n-1)}=\frac{E_{c(\max)}\zeta\omega}{\pi}\int_{t=(n-1)\pi/\omega}^{t=n\pi/\omega}\sin\Omega t\,dt$$

or

$$\phi_{p(n)}-\alpha\phi_{p(n-1)}=\frac{E_{c(\max)}\zeta}{\lambda}[\cos(n-1)\lambda-\cos n\lambda] \tag{34}$$

where $\lambda=(\pi\Omega/\omega)$. Rewriting for simplicity yields

$$\phi_{p(n)}-\alpha\phi_{p(n-1)}=C_1[\cos(n-1)\lambda-\cos n\lambda] \qquad (35)$$

where $C_1=E_{c(\max)}\zeta/\lambda$. The solution is

$$\phi_{p(n)}=C_1\left[\frac{\cos\lambda(n-1)-(\alpha+1)\cos\lambda n}{\alpha^2+1-2\alpha\cos\lambda}+\frac{\alpha\cos\lambda(n+1)}{\alpha^2+1-2\alpha\cos\lambda}\right]+\frac{C_1\alpha^n(\alpha+1)(1-\cos\lambda)}{\alpha^2+1-2\alpha\cos\lambda} \qquad (36)$$

The first term is the a-c steady-state solution while the second term represents the transient. Again, a modular differential equation may be written

$$\frac{dy}{dt}+ay=c\sin(\Omega t-\gamma) \qquad (37)$$

The complete solution of equation 37 is

$$y(t)=\frac{c\sin(\Omega t-\gamma-\theta)}{\sqrt{a^2+\Omega^2}}+\left[\frac{c\sin(\theta+\gamma)}{\sqrt{a^2+\Omega^2}}\right]\epsilon^{-at} \qquad (38)$$

where $\theta=\tan^{-1}\Omega/a$

Again it is prescribed $y(t)=\phi_{p(n)}$ for any $t=n\pi/\omega$. Hence, substituting $n\pi/\omega$ for t in equation 38, and equating the steady-state and transient terms to the corresponding terms of equation *36* results in the following relations:

$$a=\frac{\omega}{\pi}\ln\frac{1}{\alpha} \qquad (39)$$

$$c=\frac{C_1[(a+\Omega)(1-\alpha)\sin\lambda+a(1+\alpha)(\cos\lambda-1)]}{\alpha^2+1-2\alpha\cos\lambda} \qquad (40)$$

$$\sin\gamma=\frac{\Omega(\alpha-1)\sin\lambda+a(1+\alpha)(1-\cos\lambda)}{(a+\Omega)(1-\alpha)\sin\lambda+(a-\Omega)(1+\alpha)(\cos\lambda-1)} \qquad (41)$$

In the steady state, $y(t)$ lags behind the signal e_c by an angle $(\gamma+\theta)$ radians of the signal frequency. Having obtained $\phi_{p(n)}$, the half-cyclic average load current of the nth half-cycle is given as usual, by

$$I_{L(n)}=\frac{2fN_g}{R_g}\phi_{p(n-1)} \qquad (42)$$

No direct phase comparison can be established between the continuous signal e_c and the discrete values of half-cyclic average output. The instantaneous values of i_L can be obtained easily from the average half-cyclic values and a phase comparison between e_c and the fundamental (at frequency Ω) of i_L can be made as shown in Fig. 4. It is noted that, with small sinusoidal signals applied to an amplifier biased close to full output, the instantaneous output current has a fundamental component at frequency Ω that lags behind the applied signal e_c by little more than $(\gamma+\theta)$. The lag will approach $(\gamma+\theta+\lambda)$ if the amplifier is biased in the region of low outputs, i.e., a difference of phase shifts by about one half-cycle of the carrier frequency exists in the two cases.

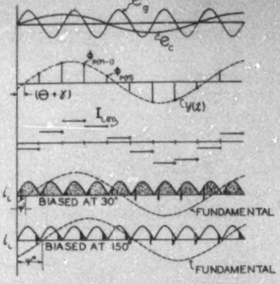

Fig. 4. Phase relationships of fundamental of output versus input for sinusoidal input voltage with two different values of bias

IV-6. EXTENSIONS OF MODULAR APPROACH TO AMPLIFIERS WITH FEEDBACK

Extensions of this approach to feedback amplifiers are possible with the use of the pertinent difference equations of the various loops. Two simple examples of magnetic and electric feedback are treated to illustrate the procedure. The results of all cases are given in Appendixes I through III.

For the amplifier with magnetic load-current feedback, Appendix II(A), equations 8 and 15 may be written. If the gate voltage and the control voltage are constant, considering incremental quantities only, equation 15 reduces to

$$I_{f(n)}=\frac{2fN_gr_s}{R_g'R_f}\phi_{p(n-1)}\pm\frac{2fN_fR_g}{R_g'R_f}(\phi_{p(n)}-\phi_{p(n-1)}) \qquad (43)$$

From the core-control curve, with constant K_ϕ

$$N_cI_{c(n)}\mp N_fI_{f(n)}=\frac{\phi_{p(n)}}{K_\phi} \qquad (44)$$

Substituting equation 43 into equation 44, solving for $I_{c(n)}$, and substituting the result into equation 8 yields

$$\phi_{p(n)}-\alpha\phi_{p(n-1)}=\zeta E_c \qquad (45)$$

where

$$\alpha=\frac{K_{BN}^*\left(1+\frac{N_f^2}{N_c^2}\frac{R_c}{R_f}\frac{R_g}{R_g'}\right)\mp\beta K_B^*}{1+K_{BN}^*\left(1+\frac{N_f^2}{N_c^2}\frac{R_c}{R_f}\frac{R_g}{R_g'}\right)} \qquad (46)$$

$$\zeta=\frac{K_\phi N_c/R_c}{1+K_{BN}^*\left(1+\frac{N_f^2}{N_c^2}\frac{R_c}{R_f}\frac{R_g}{R_g'}\right)} \qquad (47)$$

and all other symbols are defined in Appendix II(A).

The solution of equation 45 is of the same form as equation 28, i.e.,

$$\phi_{p(n)}=\frac{\zeta E_c(1-\alpha^n)}{1-\alpha} \qquad (48)$$

The load current is obtained by writing the voltage equation of the feedback loop as

$$I_{L(n)}=\left(\frac{R_f+r_s}{r_s}\right)I_{f(n)}\mp\frac{2fN_f}{r_s}\times(\phi_{p(n)}-\phi_{p(n-1)}) \qquad (49)$$

Substituting equation 43 into equation 49 and collecting terms yields

$$I_{L(n)}=C_2\phi_{p(n)}+C_3\phi_{p(n-1)} \qquad (50)$$

where

$$C_2=\pm\frac{2fN_fr_s}{R_fR_g'} \qquad (51)$$

$$C_3=\frac{2_fN_fr_s}{R_fR_g'}\left[\mp1+\frac{N_g}{N_f}\left(1+\frac{R_f}{r_s}\right)\right] \qquad (52)$$

Equation 50 shows that a step change of signal causes a change of load current already in the first half-cycle due to the transient voltage induced in the feedback loop. The modular equation is the same as equation 29 and for $y(t)$ to be equal to $\phi_{p(n)}$ at all $t=n\pi/\omega$, the conditions of equation 30 must be met. For sinusoidal signals, the difference equation of the control circuit is

$$\phi_{p(n)}-\alpha\phi_{p(n-1)}=C_1(\cos(n-1)\lambda-\cos n\lambda) \qquad (53)$$

where $C_1=\zeta E_{c(\max)}/\lambda$; λ and $E_{c(\max)}$ have been defined in section IV-5(b). The solution has the same form as equation 36. The modular equation, then, follows the same pattern as the basic, with the proper substitution of the constants pertaining to this type of feedback.

For series electric load-current feedback, Appendix III(A), equations 21 and 22 are written. On an incremental basis for constant gate voltage and constant control voltage, equation 22 becomes

$$I_{L(n)}=\frac{2_fN_g\phi_{p(n-1)}}{R_g}\mp\frac{r_s}{R_g}I_{c(n)} \qquad (54)$$

From the core-control curve, with constant K_ϕ

$$I_{c(n)}=\frac{\phi_{p(n)}}{K_\phi N_c} \qquad (54A)$$

Substituting this relationship and equation 54 into equation 21 yields

$$\phi_{p(n)}-\alpha\phi_{p(n-1)}=\zeta E_c \qquad (55)$$

where

$$\alpha=\frac{K_{EN}^{*}\mp\beta K_{E}^{*}}{1+\nu+K_{EN}^{*}} \tag{56}$$

and

$$\zeta=\frac{K_{\phi}N_c/R_c}{1+\nu+K_{EN}^{*}} \tag{57}$$

The symbols ν and β are defined in Appendix III(A).

The solution of equation 55 is

$$\phi_{p(n)}=\zeta E_c\frac{(1-\alpha^{n})}{1-\alpha} \tag{58}$$

Substituting equation 54(A) into equation 54 gives

$$I_{L(n)}=C_2\phi_{p(n)}+C_3\phi_{p(n-1)} \tag{59}$$

where

$$C_2=\mp\frac{r_s}{R_gK_{\phi}N_c} \tag{60}$$

and

$$C_3=\frac{2fN_g}{R_g} \tag{61}$$

The procedure for the modular equation follows the same pattern as for magnetic feedback.

V. Interpretation of Analytical Results

Appendixes I through III condense the results of a careful analysis which has avoided premature simplifications in the writing of circuit equations and in the process of solving. This has been done intentionally because the influence and implications of the various parameters of the system are not immediately clear in questions of magnetic amplifier feedbacks. A comprehensive formulation of all parameters is needed also as a starting point for future studies of the drift problem. As a consequence, the expressions given are moderately complex. In any specific problem, the numerical values of the various terms may suggest reasonable simplifications, as the case may be.

Some comments on the meaning of the results may be appropriate at this point. (Negative feedbacks are discussed; for positive feedbacks, of course, the trends reverse.)

The output resistance R_o, defined in Fig. 2, decreases for all types of negative load-voltage feedback (magnetic or electric) and increases for all types of negative load-current feedback. (This is the essential difference in the effects of load-voltage and load-current feedback.)

The input resistance, R_i, is not affected by magnetic feedbacks. Electric feedbacks do not modify the control winding current I_c, needed for a given output. But for negative-series electric feedback, the input resistance is increased since a larger control voltage E_c is needed to cause this I_c to flow. A negative shunt electric feedback, on the other hand, causes a larger input current I_i to be supplied from the signal source for a given I_c. The voltage E_c must be increased then to supply the additional drop across R_K; the over-all result is a decrease of R_i from the original value R_K+2r_c to a value $R_K+m\times 2r_c$, where $0<m<1$. (This is a unique feature of this type of feedback.)

The gross voltage gain K_E decreases for any type of negative feedback. The current gain, K_A decreases for negative magnetic feedback at about the same rate as K_E. For negative series electric feedback, K_A remains essentially constant, while for negative shunt electric feedback it decreases, but at a slower rate than K_E. The gross volt-ampere gain $K_{EA}=K_E\times K_A$ therefore decreases in all cases, although at different rates for the different feedbacks.

The approximate time constant τ_a, decreases proportionally to K_E if the delaying action of coupled circuits of bias or feedback is neglected. (In the case of shunt electric feedback, a delaying action arises from the resistive network connected across the control winding terminals.) On this basis, the gross voltage gain-time constant ratio (gain-bandwidth product) is invariant with any amount or type of feedback.

The modular time constant τ_y also decreases with decreasing K_E; for sufficient amounts of negative feedback it may be made smaller than the corresponding τ_a. For instance, when the voltage gain per turn K_{EN} is 1.25, the value of α, neglecting loading and coupling terms, is $\alpha=(1+1/5K_{EN}^{*})/(1+K_{EN}^{*})$. If the basic voltage gain per turn, K_{EN}^{*}, was 20 to start with, $\alpha=5/21$ and thus the modulator time constant τ_y is 7/10 of one half-cycle, while the approximate approach would suggest $\tau_a\approx 1.25$ half-cycles. Likewise for $K_{EN}=1.0$, $\alpha=1/(1+K_{EN}^{*})$, i.e., for $K_{EN}^{*}=20$, $\tau_y\approx 1/3$ of one half-cycle while τ_a is one half-cycle. (At this value of K_{EN}, however, misbehavior of rectifiers may begin to intervene significantly to reduce the accuracy of the analysis as will be seen in the next section.)

The constant C_1 of the Appendixes is used in the difference-equation analysis of sinusoidal response; C_2 and C_3 appear in the general expression for the load current $I_{L(n)}=C_2\phi_{p(n)}+C_3(\phi_{p(n-1)})$.

For quick reference, the qualitative effects of the various feedback are summed up in Appendix IV. As a final remark, it may be noted that the introduction of a forcing resistor in series with the control signal of the basic amplifier has effects similar to those of a negative series electric feedback in terms of gross voltage gain, time constant τ_a, and dynamic gain, D_p. But, of course, the series electric feedback has other features: it changes the output resistance R_o; it can stabilize an amplifier made unstable by other forms of feedback; it is helpful in linearizing the output-voltage–input-voltage characteristics over ranges of output for which K_{ϕ} is not constant and can make τ_y smaller than τ_a as seen in the foregoing.

VI. Limitations of the Analysis

Experimentation on a number of amplifiers with various feedbacks has been performed to establish the limits of validity of the assumptions.

Measured transfer characteristics of gross output voltage versus average reset mmf and also detailed observation of the wave form of instantaneous core reset voltages and reset mmf's proved that the assumption of a "core-control" curve was actually a basis quite tenable and adequate for the analytical predictions. The application of negative feedbacks, electric or magnetic, slows down the rate of reset in the prefiring interval, and increases it in the postfiring interval. These two effects tend to compensate each other fairly well in terms of the average value of the mmf of reset. Experimental transfer characteristics and oscillograms may be found in reference 2; they are omitted here. (It may be noted parenthetically that the slopes of the core-control curve depend on the gate voltage roughly proportionally over the range ±20% of normal.)

Departures from the analytical predictions began to occur when the negative feedback was increased beyond certain limits. A large negative feedback requires that the d-c signal voltage E_c be positive and large, especially at high outputs. Under these conditions, the rectifier associated with the gating core may block during an appreciable part of the prefiring interval. During this time, the resetting core remains at positive saturation, and the instantaneous control current i_c is positive, being dictated by the mmf requirements of the ascending core. All this results in a somewhat more positive value of the average mmf of reset F_p for a given output, i.e., the transfer characteristic of gross output voltage E versus F_p exhibits a pronounced droop at higher outputs.

In a typical bridge amplifier with Hypernik V, toroidal tape cores, $1^{1}/_{2}$

by 2 inches by 1/2 inch, 2 mils, and with $N_c=400$, $N_g=3{,}000$, $R_c=170$ ohms, $r_{gr}=130$ ohms, $R_g=1{,}400$ ohms at 60 cycles per second and normal gate voltage, this droop became noticeable for amounts of negative series electric or magnetic feedback which made the gross voltage gain per turn, $K_{EN}=1.25$. In terms of a transfer characteristic expressing output voltage versus input voltage, the effect is hardly noticeable because of the linearizing action of the negative feedback. The rectifier blocking effect is mentioned as a first type of departure from the assumptions of the analysis. (This effect does not occur for a-c rectified signal voltages in phase with the gate voltage as long as $K_{EN}\geq 1$.)

If the negative feedback is increased further, a more serious effect arises. The rate of reset of the resetting core $N_c\dot{\phi}$ tries to exceed the gate-limiter voltage ($-e_g$ for the bridge, and $-(1+R_L/R_g)e_g$ for the center tap), and the rectifier associated with the resetting core unblocks. Then a positive current flows in the gate winding of the resetting core which requires a compensating negative addition to the control current. These effects appear first in the region of low outputs which are associated with comparatively large swings of fluxes. This is a type of spurious positive feedback mentioned in section III-4(e), which distorts significantly the linearity of the output-input voltage characteristic. Practically, these effects occur when the voltage gain per turn becomes less than one.

These two effects, blocking and unblocking of rectifiers at improper times, violate the assumptions of the analysis. It is seen that their appearance is associated with rather extreme amounts of feedback. Experimentation on transient processes by the methods of reference 4 and by observations of rectifier voltages, failed to show any cases of rectifier misbehaviors if they did not occur in the steady state over the same range. The agreement between predicted and observed values of the modular time constant extended to values of τ_y as short as 1/4 cycle.

These considerations apply for bridge and center-tap circuitries. On the other hand, the doubler circuitries appeared particularly vulnerable to rectifier unblocking. For example, in the amplifier mentioned, in doubler connection, an amount of negative feedback, electric or magnetic, that reduced the voltage per turn from the original value, 15, to about half of that value, caused pronounced unblocking effects. This vulnerability of the doubler is due to the low value of the gate-limiter voltage as is generally known.

III. Conclusions

An analysis of 2-core full-wave self-saturating magnetic amplifiers modified by various types of electric and magnetic feedbacks has been presented. Expressions for steady-state gains and input and output resistances have been derived in terms of the gross voltage gain of the bridge amplifier, taken as the basis of reference.

With the preset flux level ϕ_p as the key variable, the transient analysis has been performed. Two different methods are employed. First, the familiar approach in which the half-cyclic average quantities are considered as continuously varying time functions has been extended to the various types of feedback circuitries. The results are given in the form of an approximate time constant τ_a. These expressions show the coupling effects inherent to magnetic and shunt electric feedbacks which are similar to that of a bias circuit coupling. The concept of the voltage gain-bandwidth product being invariant with any type and amount of feedback is seen to be only a first-order approximation.

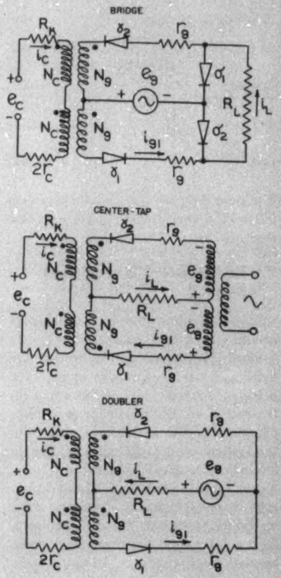
When questions of fast response arise, this approach is inadequate, and a direct solution of the difference equations is necessary. The results thus obtained include findings derived by Hubbard[5] with block diagram techniques using similar physical assumptions. The solution of the difference equation leads to a geometric progression for $\phi_{p(n)}$ but the use of an auxiliary exponential time function $y(t)$ preserves the concept of a simple time constant to describe the values of ϕ_p at the end of each half-cycle of a transient. This modular time constant τ_y has been given for the various feedbacks considered.

The half-cyclic load current $I_{L(n)}$ is obtained from the values of preset flux levels $\phi_{p(n-1)}$ and $\phi_{p(n)}$. For the basic amplifier, the half-cyclic average load current $I_{L(n)}$ depends solely on $\phi_{p(n-1)}$. Modifications by feedback introduce an additional dependency on $\phi_{p(n)}$, i.e., already in the first half-cycle the average load current is changed by some amount. In most practical cases, however, this is a minor effect and the concept of a half-cyclic time lag remains tenable for the load current.

The experiment shows that departures from the analytical predictions occurred when rectifiers blocked or unblocked at improper times in the half-cycle. In the bridge and center tap, these effects do not appear significantly, either in the steady state or transient, as long as $\tau_y \geq 1/4$ cycle. On the other hand, in the doubler, rectifier unblocking occurs for very small amounts of negative feedback, electric or magnetic. The analysis of unblocking effects in the steady state and transient requires more refined magnetic information; work is in progress along these lines for some simple cases.

Appendix I. Basic Amplifiers

The bridge, center-tap, and doubler circuits are shown in the following figure:



$$R_i=R_c$$

$$R_g=R_L+r_{gr}$$

$$R_o=r_{gr}=r_g+r_\gamma+r_\sigma$$

$$C_3 = \frac{K_E^*\frac{R_a}{r_{gr}}\left(\frac{R_1+R_2}{R_2}\right)\pm K_{EN}^*\left(1+\frac{N_b^2}{N_c^2}\frac{2r_c}{R_b}\right)}{\left[\frac{R_aR_g}{r_{gr}}\left(\frac{R_1+R_2}{R_2}\right)+\frac{R_2R_L}{R_1+R_2}\right]K_\phi\frac{N_c}{R_c}}$$

Appendix IV. Primary Effects of Negative Feedback

Table I shows the primary effects of negative feedbacks.

Neglecting delaying effects of coupled bias and feedback loops, the approximate time constant is

$$\tau_a = \frac{1}{2f}K_E\frac{N_c}{N_g} \text{ seconds}$$

The dynamic power gain (figure of merit) is

$$D_p = \frac{K_EK_A}{\tau_a} = 2f\frac{N_g}{N_c}K_A$$

Discussion

Ernest N. Costogue (Stavid Engineering Company, Plainfield, N. J.): The authors define and classify different types of feedback including resistance-shunting of rectifiers, and the common load-type feedbacks. How does resistance shunting of separate windings on magnetic-amplifier cores fit into this over-all picture, and would this be classified as a type of feedback?

R. O. Decker (Westinghouse Electric Corporation, Cheswick, Pa.): The authors are to be congratulated for their clear treatment of amplifier phenomena under transient conditions. The use of a modular time constant τ_y has merit in conveniently describing discrete values of the preset flux level ϕ_p which the authors take as the key variable of amplifier operation during transient.

The expression

$$\tau_y = \frac{\pi}{\omega}\frac{1}{\ln 1/\alpha}$$

specifies that the auxiliary variable α should be limited to values between zero and unity. When $\alpha=0$, τ_y becomes zero, and a step signal applied at the beginning of a gate supply half-cycle results in the new steady-state value of ϕ_p being established at the end of that same half-cycle. Evidently this is as fast as the amplifier can respond. It would seem, however, that negative values of α may also be obtained in practice if a sufficiently high negative feedback is introduced to modify the basic amplifier. What does this mean in terms of transient readjustments of ϕ_p and of the associated amplifier response?

L. A. Finzi and **J. J. Suozzi**: Mr. Costogue asks whether the resistance shunting of two separate windings on the two cores should be considered as a feedback and inquires about its classification within the general terminology of section I. Assume that the basic amplifier of Appendix I has been modified by adding a coil with N_a turns on each core; each coil is short-circuited directly by a resistor R_a.

Under these conditions the half-cyclic average mmf of the resetting core is modified by a term, N_aI_a. With the convention that the instantaneous current i_a is positive when flowing "into the dot," the half-cycle average mmf of the resetting core is $F_p=N_cI_c+N_aI_a$, where

$$I_a = \frac{2fN_a(\phi_s-\phi_p)}{R_a} = (E_g-E)\frac{N_a}{N_g}\frac{1}{R_a}$$

It may be said that the output variable performing feedback is the gross output voltage E, and that this feedback is negative, since a larger positive increment ΔE_c is needed now to obtain a certain increase ΔE of gross output voltage. Finally, this feedback action is obtained through windings other than the signal winding. Concluding, with the terminology of section I, this is a "negative magnetic gross-output-voltage feedback." The gain K_E is given by

$$K_E = \frac{K_E^*}{1+\beta K_E^*}$$

where

$$\beta = \frac{N_c}{N_g}\frac{R_c}{N_c^2}\Big/\frac{R_a}{N_a^2}$$

This type of feedback does not modify either the input resistance R_i or the output resistance R_o. With a simple extension of the treatment of section IV-2, the familiar result

$$\tau_a = \frac{1}{2f}K_E\frac{N_c}{N_g} \text{ seconds}$$

can be derived again. The fact that currents induced in closed loops result in a faster response may seem strange. However, the present situation should not be confused with that of a bias circuit with low resistance. In the latter case the two coils are connected in series and the induced currents have zero half-cyclic value in the steady state; the bias circuit does not affect the steady-state gain and makes itself obnoxious during the transient. In the case at hand, "induced currents" of a finite half-cyclic value flow in the steady state, and the associated reduction of voltage gain requires larger values of the swing of a signal voltage, for a wanted swing of steady-state output, to start with.

Mr. Decker notices that negative values of α are conceivable, if the amount of negative feedback is sufficiently high. The analysis is easily extended to such unusual situations, because the general difference equation

$$\phi_{p(n)} - \alpha\phi_{p(n-1)} = \zeta E_c$$

and its solution

$$\phi_{p(n)} = \frac{\zeta E_c}{1-\alpha}(1-\alpha^n) = \phi_{p\infty}(1-\alpha^n)$$

remains valid also for negative values of α. In this case, with $\alpha=-1\times|\alpha|$, the solution is rewritten in the form

$$\phi_{p(n)} = \phi_{p(\infty)}[1-(-1)^n|\alpha|^n] = \phi_{p(\infty)}[1\mp|\alpha|^n]$$

where the minus sign applies for $n=2, 4, 6$, etc. and the plus sign applies for $n=1, 3, 5$, etc. As seen in Fig. 5, $\phi_{p(2)}$, $\phi_{p(4)}$, etc., are obtained directly from the modular function, $y(t)$; its time constant may be written as

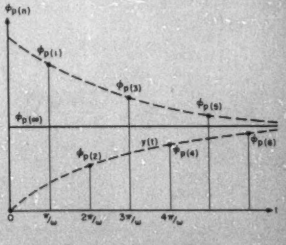

Fig. 5. Transient of preset fluxes $\phi_{p(n)}$ for $\alpha<0$

Vol
Pt.
19

$$\tau_y' = \frac{\pi}{\omega} \frac{1}{\ln 1/|\alpha|}$$

On the other hand, $\phi_{p(1)}$, $\phi_{p(2)}$, etc., are located on a curve which is symmetrical to $y(t)$ about the horizontal line, $\phi_p = \phi_{p(\infty)}$.

This behavior is explained by the general recognition that during the first half-cycle, the output remains essentially the original one and no feedback action intervenes to counterbalance the change of signal. In the limiting case $\alpha = 0$, the signal drives the resetting core exactly to $\phi_{p(\infty)}$ within the first half-cycle, and from then on steady state prevails, since the negative feedback intervenes in the subsequent half-cycles to prevent further changes of ϕ_p. When even larger amounts of negative feedback are used (so as to make $\alpha < 0$), larger values of E_c are needed for the amplifier control, and in the first half-cycle of the transient, the signal E_c "overdoes it," driving ϕ_p to a value $\phi_{p(1)}$ beyond that of the final steady state. A transient of this sort, from a lower to a higher output, is displayed in the tracing of an oscillogram; see Fig. 6. The cores and windings of the basic 60-cycle bridge amplifier are those described in section VI of the paper. The control circuit resistance is 150 ohms, and the original gains are $K_E^* = 140$ and $K_{EN}^* = 18.6$. Negative series-electric output-current feedback, Appendix III(A), has been applied with $r_s = 400$ ohms and $R_g = 1{,}500$ ohms. Hence, $\beta = 0.266$, $\gamma = 1.95$, and $\alpha \cong -0.865$. Accordingly

$$\tau_y' = \frac{1}{2f} \frac{1}{\ln 1/|\alpha|} = 0.057 \text{ seconds}$$

i.e., somewhat less than 7 half-cycles. The effects discussed in section VI for high values of negative feedback limit somewhat the validity of the analysis, but the agreement between this analytical prediction and the oscillographic results shown is still quite good.

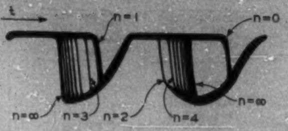

Fig. 6. Wave forms of load voltage in a transient from low to high outputs. Negative series-electric output-current feedback with $\alpha \approx -0.865$

A General Approach for Obtaining Transient Response by the Use of a Digital Computer

P. E. LEGO
ASSOCIATE MEMBER AIEE

T. W. SZE
MEMBER AIEE

OBTAINING the transient response of linear systems is fundamentally a problem involving the solution of the differential equations which describe the behavior of the system. These equations can be solved by the use of classical methods, operational calculus, or by applying the Laplace transformation.

It is not always possible, however, to obtain the equations describing the system response, or if obtainable these equations may be extremely difficult to solve analytically. For example, the inverse Laplace transform requires the determination of the roots of the characteristic equation of the differential equations. For feedback systems with transport delay in the forward loop, difference differential equations are produced which include exponential terms or exponential coefficients. The characteristic equation of such systems has an infinite number of roots which cannot be found in the usual manner. Also, at times the only information available concerning a particular system may be frequency response data. For these reasons other methods have been developed for finding the time response of linear systems.

There are many different methods available for finding the time response, from frequency response data, of linear systems to unit impulse, unit step, or other arbitrary inputs. An excellent description and comparison of many of these methods is given by Donegan and Huss.[1]

The methods classified as "inverse transform methods" were found to be most effective in determining the response, to a unit impulse from frequency response data, of higher order systems. These methods are all based on the evaluation of the form of the inverse transform equation, equation 1, for positive values of time.

$$h(t) = \frac{2}{\pi} \int_0^\infty R_e[F(jw)] \cos twdw \qquad (1)$$

where:

$h(t)$ = time response of a system to a unit impulse
$F(jw)$ = frequency response of a system
$j = \sqrt{-1}$
t = time in seconds
w = angular frequency, radians per second

This equation has the disadvantage that if the system has an even-order pole at the origin, $R_e[F(jw)]$ will be infinite as w approaches zero. Also $R_e[F(jw)]$ in general will not approach zero quickly and, therefore, a large frequency range must be covered in the evaluation.

The accuracy of the Fourier method depends on the choice of a fundamental frequency w_f, which is quite difficult for high-order systems. The other methods either require previous knowledge of the form of the transfer function relating the system input and output or do not produce the required accuracy for higher order systems.

A graphical method, based on a different Fourier integral representation of the unit step function, has been developed by T. W. Sze[2] which will permit the finding of time response for systems containing delay functions. This method is also applicable to the finding of time response from frequency response data for any stable linear system. It has the particular attribute of eliminating the difficulties encountered with the Fourier and inverse Laplace transform methods for finding time response from frequency response data.

A different approach which produces the same end result as Sze's method may be found in a paper by A. Leonhard.[3]

Included in this paper will be two digital techniques for obtaining the transient response of linear control systems. The first is based on the conventional method of inverse Laplace transformation. The second is based on a Fourier integral

Digital Computer Technique Based on Inverse Laplace Transformation

This section is concerned with systems whose behavior is known in the form of a system transfer function, which is a general rational algebraic proper fraction in the Laplace variable s, or in the form of a linear integro-differential equation from which the system transfer function may be derived.

In order to obtain the system time response, the process of inverse Laplace transformation must be performed on these transfer functions. This is a difficult, tedious procedure, especially for high-order systems.

A digital computer program has been developed, using the IBM (International Business Machines Corporation) *704* digital computer, which performs the inverse Laplace transformation of the following expression:

$$Q(s)=\frac{A(s)}{B(s)}=\frac{a_ms^m+a_{m-1}s^{m-1}+\ldots+a_1s+a_0}{b_ns^n+b_{n-1}s^{n-1}+\ldots+b_1s+b_0},\ (n>m) \tag{2}$$

This program contains the following restrictions:

1. The degree of the denominator, n, must be ≤ 30.
2. If there are multiple poles, the multiplicity of the pole is limited to four or less.

For computers of different varieties, these restrictions may be altered depending mainly on the memory capacity of the computer. One program with somewhat more stringent restrictions and applications was developed by Titus for use on a smaller computer.[4]

This program has the additional feature that it not only gives the residues and coefficients of all poles, but also calculates the magnitudes of system transient response at specified instants of time.

The logic of this program is presented in the flow diagram shown in Fig. 1. This logic is based on the conventional partial fraction expansion method for finding inverse Laplace transforms.

Digital Computer Technique Based on Fourier Integral Representation of Transient Response

In reference 1, the survey of different methods of obtaining system transient response placed these methods into several different categories and classified them as follows:

1. Inverse Laplace transformation methods:
   - (*a*). Floyd's method.
   - (*b*). Numerical integration method.
   - (*c*). Rectangular pulse method.
2. Fourier method.
3. Other methods:
   - (*a*). Schumaker's method.
   - (*b*). *P*-transform method.

In reviewing these methods, it has been found that they all require information on the system transfer function or system frequency reponse data. On the latter, the methods are mainly based on the integral relation shown in equation 1. The disadvantages of this integral have already been stated. A new relation for obtaining the transient response which overcomes these disadvantages will be shown here.

Theoretical Derivation

The general form of the Fourier integral in its exponential form is

$$f(t)=\frac{1}{2\pi}\int_{-\infty}^{\infty}dw\int_{-\infty}^{\infty}e^{jw(t-u)}f(u)du \tag{3}$$

Let $F(p)$ be an operational function in which the differential operator $p=d/dt$. Thus $F(p)[f(t)]$ means that $F(p)$ operates on $f(t)$.

$$F(p)[f(t)]=\frac{1}{2\pi}\int_{-\infty}^{\infty}dw\int_{-\infty}^{\infty}F(jw)e^{jw(t-u)}\times f(u)du \tag{4}$$

If $f(t)$ is a unit step function, and $F(p)$ is the system transfer function in operational form, the transient response to a unit step input is $q(t)=F(p)[f(t)]$, which is the integral of equation 4. To simplify equation 4, assume that $F(jw)=R(w)+jI(w)$. Then

$$q(t)=\frac{1}{2\pi}\int_{-\infty}^{\infty}dw\int_{-\infty}^{\infty}[R(w)\cos w(t-u)-I(w)\sin w(t-u)]f(u)du+j\frac{1}{2\pi}\int_{-\infty}^{\infty}dw\int_{-\infty}^{\infty}[I(w)\cos w(t-u)+R(w)\sin w(t-u)]f(u)du \tag{5}$$

Since $F(p)$ is a real operator for a physical system and $f(t)$ a real function, $q(t)$ should also be a real function. Thus the imaginary part of equation 5 must vanish.

$$q(t)=F(p)[f(t)]=\frac{1}{2\pi}\int_{-\infty}^{\infty}dw\int_{-\infty}^{\infty}\times[R(w)\cos w(t-u)-I(w)\sin w(t-u)]\times f(u)du \tag{6}$$

With the conventional representation, that $f(t)=1$ for $t>0$ and $f(t)=0$ for $t\leq 0$, the integral equation 3 does not exist since the integral of $f(t)$ over the infinite range becomes infinite. Here, the conventional representation of the unit step function is left and a new function $U(a,t)$ is named which has the following properties:

$$\lim_{a\to 0}U(a,t)=1 \quad \text{for } t>0$$
$$U(a,t)=0 \quad \text{for } t\leq 0$$
$$\lim_{t\to\infty}U(a,t)=0 \quad \text{for } a>0 \tag{7}$$

It is sufficient to select for this function

$U(a,t) = e^{-at}$ for $t > 0$. Substituting this function for $f(u)$ in equation 6,

$$F_a(p)[f(t)] = \frac{1}{2\pi}\int_{-\infty}^{\infty} dw \int_{-\infty}^{\infty} \times$$

$$[R(w)\cos w(t-u) - I(w)\sin w(t-u)]e^{-au}du$$

$$= \frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{R(w)w\sin tw}{a^2+w^2}\,dw + \frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{I(w)w\cos tw}{a^2+w^2}\,dw + \frac{a}{2\pi}\int_{-\infty}^{\infty} \frac{R(w)\cos tw - I(w)\sin tw}{a^2+w^2}\,dw \quad (8)$$

Taking the limit as a approaches zero, equation 8 becomes $F(p)[f(t)]$ or $q(t)$:

$$q(t) = \lim_{a\to 0}\left[\frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{R(w)w\sin tw}{a^2+w^2}\,dw + \frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{I(w)w\cos tw}{a^2+w^2}\,dw + \frac{a}{2\pi}\int_{-\infty}^{\infty} \frac{R(w)\cos tw - I(w)\sin tw}{a^2+w^2}\,dw\right] \quad (9)$$

The evaluation of these limits yields:

$$\lim_{a\to 0}\frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{R(w)w\sin tw}{a^2+w^2}\,dw = \frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{R(w)\sin tw}{w}\,dw \quad (10)$$

$$\lim_{a\to 0}\frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{I(w)w\cos tw}{a^2+w^2}\,dw = \frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{I(w)\cos tw}{w}\,dw \quad (11)$$

$$\lim_{a\to 0}\frac{a}{2\pi}\int_{-\infty}^{\infty} \frac{R(w)\cos tw - I(w)\sin tw}{a^2+w^2}\,dw = \frac{1}{2}F(0) \quad (12)$$

The proof for equation 12 is shown in the Appendix. Thus

$$q(t) = F(p)[f(t)] = \frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{R(w)\sin tw}{w}\,dw + \frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{I(w)\cos tw}{w}\,dw + 1/2F(0) \quad (13)$$

Since $R(w)$ and $I(w)$ are the real and the imaginary part of the system transfer function $F(jw)$, $R(w)$ is then an even function and $I(w)$ is an odd function. Thus both $R(w)\sin tw/w$ and $I(w)\cos tw/w$ are even functions, and equation 13 may be rewritten as

$$q(t) = \frac{1}{\pi}\int_{0}^{\infty} \frac{R(w)\sin tw}{w}\,dw + \frac{1}{\pi}\int_{0}^{\infty} \frac{I(w)\cos tw}{w}\,dw + \frac{1}{2}F(0) \quad (14)$$

Fig. 2. Flow diagram of Fourier integral program

In a transient response study, the step function is applied at $t=0$. The system is assumed to be at rest prior to $t=0$, i.e.,

$$q(-t) = 0$$

or

$$-\frac{1}{\pi}\int_{0}^{\infty} \frac{R(w)\sin tw}{w}\,dw + \frac{1}{\pi}\int_{0}^{\infty} \frac{I(w)\cos tw}{w}\,dw + \frac{1}{2}F(0) = 0 \quad (15)$$

or

$$\frac{1}{\pi}\int_{0}^{\infty} \frac{R(w)\sin tw}{w}\,dw = \frac{1}{\pi}\int_{0}^{\infty} \frac{I(w)\cos tw}{w}\,dw + \frac{1}{2}F(0) \quad (16)$$

Here the final forms of transient response due to a unit step input relating to the frequency response data are written as

$$q(t) = \frac{2}{\pi}\int_{0}^{\infty} \frac{R(w)\sin tw}{w}\,dw \quad (17A)$$

$$q(t) = \frac{2}{\pi}\int_{0}^{\infty} \frac{I(w)\cos tw}{w}\,dw + F(0) \quad (17B)$$

In all physical systems, $F(jw)$ eventually approaches zero as the frequency increases. Thus $R(w)/w$ and $I(w)/w$ are both asymptotic to zero. Suppose that the values $R(w)/w$ and $I(w)/w$ become negligible when w reaches w_1 and w_2 respectively. The equations 17(A) and 17(B) may be written as

Fig. 3. Block diagram of a Taylor's series compensator series-compensated system

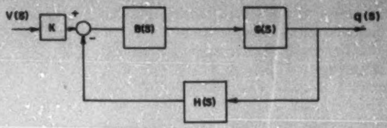

Fig. 5. Block diagram of a Taylor's series compensator feedback-compensated system

$$q(t_k)=\frac{2}{\pi}\int_0^{w_1}\frac{R(w)}{w}\sin t_k w\,dw \qquad \text{(18A)}$$

or

$$q(t_k)=\frac{2}{\pi}\int_0^{w_2}\frac{I(w)}{w}\cos t_k w\,dw+F(0) \qquad \text{(18B)}$$

Either of the two forms of integrals can be used in evaluating the transient response. However, two factors usually decide the choice. One factor is whether $R(w)/w$ or $I(w)/w$ approaches zero faster. This means to choose a smaller frequency range to be covered in computing the integral. The other factor depends on the system transfer function itself; whether the integral becomes nonexistent or indeterminant. For example, if the system has a pole at the origin, then $F(0)=$infinity, and that eliminates the use of equation 18(B). On the other hand, if the system is of a type of proportional control, then $R(0)$ is not equal to zero, and $\lim_{w\to 0} R(w)/w=$infinity. Under this condition, equation 18(A) should not be used.

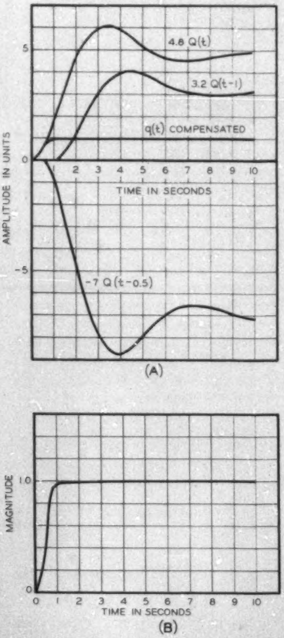

Fig. 4. Transient response to a unit step of Taylor's series compensator series-compensated second-order system

A—As given by inverse Laplace transform routine

B—As given by Fourier integral routine

In using the $I(w)/w$ curve, however, the value of $I(w)/w$ at $w=0$ is an indeterminant value and must be evaluated first. Its limiting value as w approaches zero can be obtained by applying L'Hospital's rule:

$$\lim_{w\to 0}\frac{I(w)}{w}=\lim_{w\to 0}\frac{\frac{d}{dw}I(w)}{1}=\frac{d}{dw}[I(w)]_{w=0}$$

$$=\text{initial slope of the } I(w)$$

curve versus w.

Transient Response Due to Unit Rate, Unit Acceleration, or Unit Impulse Input

Once the transient response $q(t)$ due to a unit step input is obtained, the transient response due to a unit rate or unit acceleration input may be evaluated by the use of the convolution integral. Thus

$r(t_k)=$transient response due to unit rate input

$$=\int_0^{t_k} q(t)dt \qquad (19)$$

$h(t_k)=$transient response due to unit acceleration input

$$=\int_0^{t_k} r(t)dt \qquad (20)$$

$i(t_k)=$transient response due to unit impulse input

$$=\left[\frac{d}{dt}\,q(t)\right]_{t=t_k} \qquad (21)$$

Computer Adaptation to the Preceding Fourier Method

A digital computer program has been developed for the IBM *704* computer based on the preceding method. The program is adapted to cases where the system transfer function is known and will compute the necessary frequency data. The program also handles those cases for which $R(w)$ and $I(w)$, or only frequency response data of the system, are known.

The logic of this program is shown by the flow diagrams of Figs. 2(A) and 2(B). Fig. 2(A), in conjunction with Fig. 2(B), shows the steps necessary when the system transfer function is the beginning point of the solution. Fig. 2(B), alone, shows the steps needed when frequency data are available to begin the problem.

Two examples are calculated to show the results of the computer programs.

EXAMPLE 1

This example was selected because it is possible to solve it by the conventional Laplace transform method as well as the Fourier integral method.

The system shown in block diagram form in Fig. 3 uses a delay line in series compensation. Using the data

$$B(s)=4.8-7e^{-0.5s}+3.2e^{-s} \qquad (22)$$

$$G(s)=\frac{1}{1+0.8s+s^2} \qquad (23)$$

with a unit step function as the input the system response function is

$$q(s)=\frac{4.8-7e^{-0.5s}+3.2e^{-s}}{s(1+0.8s+s^2)} \qquad (24)$$

The inverse Laplace transform gives $q(t)$, the transient response, as

$$q(t)4=.8Q(t)-7Q(t-0.5)+3.2Q(t-1)$$

where

$$Q(t)=1+1.091e^{-0.4t}\sin(0.916t-113.6\text{ degrees}) \qquad (25)$$

This response is found using the digital computer program for the inverse Laplace Transform and is plotted on Fig. 4(A).

The Fourier method calculates the response to a unit step function directly from the system transfer function given in equation 26.

$$F(s)=\frac{4.8-7e^{-0.5s}+3.2e^{-s}}{1+0.8s+s^2} \qquad (26)$$

The digital computer solution to this problem is shown in Fig. 4(B). A comparison of the results shows agreement within 0.5 per cent.

EXAMPLE 2

This method is selected so that the transient response cannot be found by

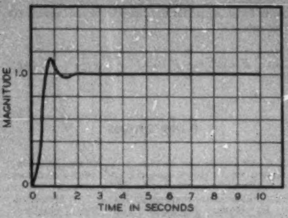

Fig. 6. Transient response to a unit step of a Taylor's series compensator feedback-compensated second-order system as given by Fourier integral routine

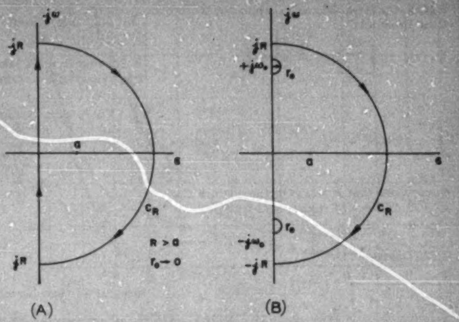
Fig. 7. Contour integration of analytic function $\psi(z)$

A—F(z) having no pole on imaginary axis

B—F(z) having conjugate pairs of poles on imaginary axis



the conventional inverse Laplace transform method since the number of poles is infinite. However, beginning with the system transfer function, or with frequency response data, the transient response may be found using the Fourier integral method described in this paper.

The block diagram of the system is shown in Fig. 5. Using the data

$$H(s)=0.4 \tag{27}$$

$$B(s)=4.8-7e^{-0.8s}+3.2e^{-s} \tag{28}$$

$$G(s)=\frac{1}{1+0.8s+s^2} \tag{29}$$

$$K=1.4 \tag{30}$$

the system transfer function may be expressed as

$$F(s)=\left[\frac{4.8-7e^{-0.8s}+3.2e^{-s}}{1+0.8s+s^2+(0.4)(4.8-7e^{-0.8s}+3.2e^{-s})}\right]1.4 \tag{31}$$

The unit step response of this system is calculated by the digital computer program directly from this transfer function. The result is shown in Fig. 6.

Conclusions

The adaptation of digital computers to the inverse Laplace transformation process and the Fourier integral method provides many advantages. The major advantages are as follows:

1. They offer a generalized technique for obtaining the transient response of a linear system.

(*a*). The digital program for the inverse Laplace transformation method, although limited to a system of 30th order or less with a multiplicity of poles of four or less, will solve most complex linear systems.

(*b*). The digital program for the Fourier integral method imposes no limit on the order of the system or the multiplicity of poles. Therefore, the program will handle any system so long as it is known to be linear and stable.

2. The Fourier integral method offers a process for obtaining the transient response of systems whose response cannot be found by the conventional Laplace transformation method. This method applies to the cases where only frequency response data of the the system is known, or where the system contains a characteristic equation which cannot be solved by conventional methods. This process, naturally, may be carried out without the use of a digital computer by using graphical integration and approximation.[2,3] It is, however, a tedious and time-consuming process, with a lower degree of accuracy, than a system designer would hesitate to attempt. With the digital computer in increasing use and availability, methods that usually require tremendous effort and time, may be carried out on the computer with ease. For instance, example 2 of this paper was carried out by graphical integration, using Simpson's rule, and by computer application. The former process took approximately 40 hours, using 20 intervals for integration. The latter took 3½ minutes, including input and output time, while using 100 intervals for integration by Simpson's rule.

3. The availability of these programs enables the designer to apply the Laplace transform technique to problems where the task of obtaining the Inverse Laplace Transform previously made this solution too difficult to undertake.[5]

Appendix. Proof of Equation 12

Equation 12 is stated as

$$\lim_{a\to 0}\frac{a}{2\pi}\int_{-\infty}^{\infty}\frac{R(w)\cos tw-I(w)\sin tw}{a^2+w^2}\,dw=\frac{1}{2}F(0) \tag{12}$$

This limit can be proved as follows.

The integral, equation 12, can be written

$$\frac{a}{2\pi}\int_{-\infty}^{\infty}\frac{R(w)\cos tw-I(w)\sin tw}{a^2+w^2}dw=\frac{a}{2\pi}\Re\left[\int_{-\infty}^{\infty}\frac{F(jw)e^{jtw}dw}{a^2+w^2}\right]=\frac{a}{2\pi}\Im\left[\int_{-j\infty}^{j\infty}\frac{F(jw)e^{jtw}d(jw)}{a^2-(jw)^2}\right] \tag{32}$$

This integral can be evaluated by a contour integration in the complex plane. Choose an analytic function $\psi(z)$ such that $\psi(z)=F(z)e^{tz}/a^2-z^2$, where $F(z)$ is known not to possess any pole on the right half side of the complex plane. Thus the only pole on the right half plane is at $z=a$. Integrate $\psi(z)$ in a clockwise direction around the boundary of the semicircle region, as shown in Figs. 7(A) and 7(B).

If $F(z)$ has no pole on the imaginary axis, the contour as shown in Fig. 7(A) will be used. Otherwise use the contour for integration as shown in Fig. 7(B). The semicircle has a radius R where $R>a$ so that the pole at $Z=a$ is enclosed. Thus by the Residue Theorem,

$$\oint\psi(z)dz=-2\pi jK_1 \tag{33}$$

where K_1 is the residue of $\psi(z)$ at the pole $z=a$, and the negative sign is due to the clockwise direction of contour integration. And

$$K_1=\lim_{z\to a}\frac{\dfrac{F(z)e^{tz}}{a^2-z^2}}{z-a}=\frac{-F(a)e^{at}}{2a} \tag{34}$$

Therefore

$$\oint\psi(z)dz=j\frac{\pi F(a)e^{at}}{a} \tag{35}$$

If $F(z)$ has poles on the imaginary axis, then from Fig. 7(B)

$$\oint\psi(z)dz=\int_{-jR}^{-j(w_0+r_0)}\psi(jw)d(jw)+\int_{-\pi/2}^{\pi/2}\psi(-jw_0+r_0e^{j\theta})d(r_0e^{j\theta})+\int_{-j(w_0-r_0)}^{j(w_0-r_0)}\psi(jw)d(jw)+\int_{-\pi/2}^{\pi/2}\psi(jw_0+r_0e^{j\theta})d(r_0e^{j\theta})+\int_{j(w_0+r_0)}^{jR}\psi(jw)d(jw)+\int_{C_R}\psi(z)dz \tag{36}$$

where C_R represents the right half of a circle with $z=R$, $(R>a)$. The limit of the integral, equation 36, as r_0 approaches zero then becomes:

$$\oint \psi(z)dz = \int_{-jR}^{jR} \psi(jw)d(jw) + \int_{C_R} \psi(z)dz \tag{37}$$

Thus

$$\int_{-jR}^{jR} \psi(jw)d(jw) = j\frac{\pi F(a)e^{at}}{a} - \int_{C_R} \psi(z)dz \tag{38}$$

everywhere that $R>a$. On the contour C_R, $|Z|=R$, or $Z=Re^{j\theta}$ with $-\pi/2 \leqq \theta \leqq \pi/2$,

$$|a^2-z^2| \leqq a^2-|z^2| = a^2-R^2$$

Consequently,

$$\left|\int_{C_R} \psi(z)dz\right| \leqq \int_{C_R} \frac{|F(z)|\,|e^{tz}|\,|dz|}{a^2-R^2}$$

$$= \int_{\pi/2}^{-\pi/2} \frac{|F(re^{j\theta})|\,|jRe^{j\theta}|\,|d\theta|}{a^2-R^2}$$

$$= \int_{\pi/2}^{-\pi/2} \frac{|F(Re^{j\theta})|\,Rd\theta}{a^2-R^2}$$

For a physical system with a transfer function of $F(jw)$, the limit of $F(Re^{j\theta})$ approaches zero as R approaches infinity. Also, since R has a higher power in the denominator than the numerator,

$$\lim_{R\to\infty}\left|\int_{C_R} \psi(z)dz\right| = 0 \tag{39}$$

From equation 38, taking the limit as $R\to\infty$, the following is obtained:

$$\int_{-j\infty}^{j\infty} \psi(jw)d(jw) = \lim_{R\to\infty}\int_{-jR}^{jR} \psi(jw)d(jw)$$

$$= j\frac{\pi F(a)e^{at}}{a} -$$

$$\lim_{R\to\infty}\int_{C_R} \psi(z)dz$$

$$= j\frac{\pi F(a)e^{at}}{a} \tag{40}$$

Integral 32 then becomes

$$\frac{a}{2\pi}\mathscr{J}\left[\int_{-j\infty}^{j\infty} \frac{F(jw)e^{jtw}d(jw)}{a^2-(jw)^2}\right]$$

$$= \frac{a}{2\pi}\mathscr{J}\left[\int_{-j\infty}^{j\infty} \psi(jw)d(jw)\right]$$

$$= \frac{a}{2\pi}\left[\frac{\pi F(a)e^{at}}{a}\right]$$

$$= \frac{1}{2}F(a)e^{at} \tag{41}$$

Now as a approaches zero the integral 40 becomes

$$\lim_{a\to 0}\frac{1}{2}F(a)e^{at} = \frac{1}{2}F(0) \tag{42}$$

Digital Calculation of Transient Performance of the Primary Coolant System in a Water Reactor

D. G. LEWIS
ASSOCIATE MEMBER AIEE

IN THE DESIGN of control systems for nuclear reactors, detailed knowledge of the rate of change of temperature in the reactor core is a very important factor. To evaluate this temperature as a function of time, it is necessary to determine both the heat added from the nuclear reaction itself, and the heat rejected through the cooling medium and through losses. The ability of the cooling medium to remove heat from the reactor is dependent upon the rate of coolant flow. This paper describes an application of a digital computer for computing coolant flow under various transient conditions which may arise during normal operation or during emergencies. The method used takes into account the following factors:

1. Inertia of the coolant fluid.
2. Inertia of rotating equipment (pumps and motors).
3. Frictional pressure drops in the flow paths.
4. Pump head flow characteristics.
5. Friction and windage losses in pumps and motors.
6. Transient effects in the rotor circuits of the pump motors.

Note that free convection of the fluid is not considered. Because of the heat transfer to and from the coolant, and because of the configuration of the flow paths, pressure heads are developed which result in a free convection component of flow. This component of flow becomes significant only when the total flow is less than 5% of normal flow. For flows greater than this, free convection may be safely ignored.

The flow paths in the coolant system are shown in Fig. 1. It is a 2-loop system as shown, so named because of the two parallel fluid paths, each with its own pump and driving motor. The flows in these two loops are not independent of each other, since the flow path through the reactor itself is common to both loops. The situation is analogous to that of a mutual impedance in a 2-loop electrical circuit, except that in the fluid case, the drop in potential (pressure) is not a linear function of the flow.

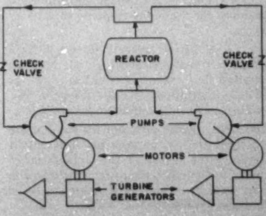

Fig. 1. Two-loop system arrangement

Paper 58-1314, recommended by the AIEE Computing Devices and Nucleonics Committees and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted June 30, 1958; made available for printing September 11, 1958.

D. G. Lewis is with the General Electric Company, Schenectady, N. Y.

A portion of the material for this paper was obtained in the course of engineering development work under Contract No. *W-31-109 Eng-52*, sponsored by the General Electric Company which operates the Knolls Atomic Power Laboratory for the United States Atomic Energy Commission.

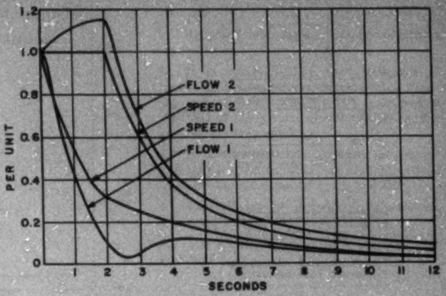

Fig. 3. Sequential failure. Motor 1 open-circuited at t=0, motor 2 open-circuited at t=2.0 seconds

In the system studied, the basic configurations of the two loops are identical. Thus the physical parameters of the two loops are the same, although the instantaneous flows and motor speeds may differ.

Energy to drive the coolant fluid is supplied by the pumps, which in turn are driven by induction motors supplied from individual generators. Each fluid loop has a check valve to prevent reverse flow, and it is also equipped with stop valves as required for control and maintenance.

In studying the flow in this system from the standpoint of protection against overheating of the reactor during emergencies, the important quantities to be determined are the total and loop flows and the motor speeds as functions of time. Quantities of secondary importance, but often needed in the design of protective arrangements, are the motor torques, currents, and rotor flux-linkages. To obtain these quantities, the differential equations for the system have been derived, and a digital computer has been used to develop particular solutions of these equations for cases of interest. The analytical approach and the numerical method for solving the differential equations are described in the section "Outline of Analysis and Computer Programming."

Transient Performance of Coolant System

Since the physical parameters of the two loops are the same, any operating condition or disturbance which affects both of the loops in exactly the same way can be analyzed much more easily than a disturbance which causes different conditions to exist in the two loops. The former case is referred to as a "symmetrical" case, the latter as a "nonsymmetrical" case. The equations and computer program for this study were developed to apply to nonsymmetrical cases, but can be used for symmetrical cases also.

The first set of results shown, Fig. 2, compares computed results with test data for a symmetrical case.[1] For this case, both loops are assumed to be operating in the steady state under rated conditions prior to the disturbance. At time zero, the pumps in both loops fail, due to sudden opening of the motor breakers. The curve shows the resulting decay of flow. The close agreement between the computed and test data indicates that both the differential equations and the numerical method used to solve them are a satisfactory approximation, despite the limitations inherent in the transient analysis of the electrical and fluid systems.

Fig. 3 shows both flows and speeds for both loops for a nonsymmetrical case. For this run, the initial conditions and the type of disturbance are the same as for the run of Fig. 2, except that the failure occurs in loop 1 at time zero and in loop 2 at $t=2.04$ seconds.

Fig. 4 shows flow, speed, and rotor flux linkage for another symmetrical case, namely, sudden loss of field on the generators supplying the pump motors. For this case, the motor currents and torques were also computed.

The computer program used to obtain these results has been used to study other cases as well, including loss of steam pressure on the turbine generators, 3-phase short circuits on the pump motors, motor shaft failure, and seizure of the pump impeller. Each of the cases requires some modification of the computer program, but the same basic program can be used for many different conditions as long as care is observed in making program changes correspond to changes in the physical system.

Outline of Analysis and Computer Programming

The general analysis of the system of Fig. 1 proceeds as follows: The equations of a multiloop fluid system are derived from the equations of Lagrange.[2] The force terms in these equations are then

related to the pump shaft torque by means of the steady-state pump head-flow characteristics. This shaft torque is obtained from the motor electrical torque less friction and windage terms. The motor torque can be calculated from motor current and flux linkages which are obtained in turn, by the 2-axis induction motor equations used previously to study the transient performance of induction motors.[3,4] These developments provide a set of four first-order differential equations for dependent variables in each loop of the system. Thus, in the 2-loop system, eight simultaneous first-order differential equations must be solved. The initial (steady-state) values of the dependent variables in these equations can be obtained quite easily. The equations are nonlinear, however, and a solution by numerical methods is required unless extensive simplifications are made. The number of equations and the variety of cases to be studied makes the use of automatic computing equipment mandatory. When this problem was first proposed, it was evident that it would arise repeatedly with different sets of physical constants to be considered. This, together with the necessity of representing accurately several important nonlinearities and the use of tabulated pump characteristics, led to the conclusion that a flexible digital computer program would be superior to an analog computer setup. Such a program was written for the International Business Machines Corporation *650* computer, and the results shown in Figs. 2 through 4 were obtained with this program. Complete results for symmetrical cases similar to those illustrated by Figs. 2 and 4 are obtained in about 20 minutes. For nonsymmetrical cases, such as the one illustrated by Fig. 3, complete results are obtained in about 40 minutes. A corresponding program has been written for the IBM *704* computer.

The computer program is divided into three main sections:

1. Calculation of derivatives.
2. Step-by-step numerical integration.
3. Output program.

The separation of the first two sections follows from the usual approach to numerical solutions of initial-value problems. Such a problem is expressible as a set of differential equations of the form

$$\begin{aligned}\frac{dy_1}{dt} &= f_1(t, y_1, y_2 \ldots y_n)\\ \frac{dy_2}{dt} &= f_2(t, y_1, y_2 \ldots y_n)\\ &\vdots\\ \frac{dy_n}{dt} &= f_n(t, y_1, y_2, \ldots y_n)\end{aligned} \qquad (1)$$

In the problem at hand, $n=8$, and the y's correspond to the flows, speeds, and motor flux linkages which appear as dependent variables in the system equations. The solution of such a problem can be obtained with several different numerical procedures of varying complexity and accuracy.[5,6] All of these methods, however, use the derivatives obtained from equation 1 together with values of the dependent variables known at a point t_k (or several points t_k, t_{k-1}, etc.) to obtain values of the variables at the point t_{k+1}. Repeated applications of this process, for which the term "step-by-step" is commonly used, give values of the dependent variables for any desired excursion of the independent variable, which in this problem is the time t.

To allow relative ease in making program modifications, the section of the computer program used for the calculation of derivatives was further subdivided. By keeping these subdivisions carefully identified, the chances for error in making program changes were substantially reduced. Fig. 5 illustrates the rather obvious nature of the these subdivisions and shows the sequence in which they occur as the derivative calculation is executed.

The step-by-step method used in the *650* program for this problem is known as the modified Euler's method and is often referred to as "slope extrapolation with trapezoidal improvement." It consists of the application of the two following equations.

Predictor (slope extrapolation):

$$y_j\Big|_{k+1}^{P} = y_j\Big|_{k}^{C} + \Delta t\left[f_j(t, y_1, y_2 \ldots y_j y_n)\Big|_{k}^{C}\right] \qquad \mathbf{(2)}$$

Corrector (trapezoidal improvement):

$$y_j\Big|_{k+1}^{C} = y_j\Big|_{k}^{C} + \frac{\Delta t}{2}\left[f_j(t, y_1 \ldots y_n)\Big|_{k}^{C} + f_j(t, y_1 \ldots y_n)\Big|_{k+1}^{P}\right] \qquad \mathbf{(2A)}$$

It can be seen that this corrector equation can be applied repeatedly at the point t_k until no further significant improvement can be obtained. However, since the evaluation of derivatives indicated by equations 1 must be made for each improvement, it is usually found most economical to make a single improvement as

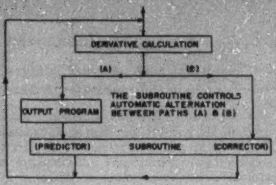

Fig. 7. Over-all flow diagram

in equation 2(A), reducing the integrating interval Δt if greater accuracy is needed. Fig. 6 illustrates the application of this method.

By separating the numerical integration section of the program from the other sections it is possible to write it in the form of a subroutine, with general features which allow it to be used for the solution of other sets of differential equations. Such a subroutine was developed in the work on this particular problem, and has been used successfully for other problems, such as the calculation of missile trajectories and the analysis of transient performance of groups of induction motors.[7]

The output program is made separate from the other sections for the following reasons:

1. It is not necessary to produce output data at each step in the numerical integration procedure.
2. Some of the desired output data is not normally computed during the evaluation of derivatives. These include magnitudes and angles of current and flux linkage which are normally computed in the form of rectangular components (α-β quantities).

Fig. 7 shows how the three sections of the program are used together to obtain the desired over-all operation.

Conclusions

A medium-sized digital computer, with a flexible program, provides a fast and economical way to study the transient performance of electromechanical-fluid systems if that performance can be defined by a set of ordinary first-order differential equations. Nonlinearities usually inherent in these systems can be handled readily by numerical methods. The necessity of considering a wide variety of transient disturbances means that the computer program must be modified frequently, but this can be done easily if care is taken to subdivide the program in correspondence with the actually separate parts of the physical system itself.

Appendix I. Nomenclature and Assumptions

Nomenclature

t = time
T = kinetic energy
U = potential energy
Q = generalized force
m = mass
v = velocity
l = length of flow path
A = area of flow path
g = acceleration of gravity
ρ = density
W = flow rate
ω = pump impeller and motor speed
ΔP_p = pump pressure rise
ΔP_L = frictional pressure drop in loop portion of flow path (not common to both loops)
ΔP_R = friction pressure drop in common portion of flow path (reactor)
$\Sigma l/A$ = geometry-dependent inertia factor for element of flow path
η_p = impeller efficiency
H_L = loop inertia factor
H_R = common path inertia factor
H_M = inertia factor for motor and impeller
T_M = mechanical torque
T_E = electrical torque
K_W = friction and windage loss coefficient
D = rotor diameter
L = rotor length
$\left.\begin{matrix}K\\A\\B\end{matrix}\right\}$ = constants defined when used
E = motor terminal voltage
I = motor armature current
ψ = motor rotor flux linkages
X = motor transient reactance: $X = L_s - M^2/L_r$
r = rotor resistance
r_M = resistance in magnetizing branch of motor equivalent circuit
M = mutual inductance
L_r = rotor self-inductance
L_s = stator self-inductance

Subscripts:

L = loop
R = reactor
$\left.\begin{matrix}1\\2\end{matrix}\right\}$ = loops 1 and 2
O = initial or rated value
N = normalized value
B = base quantity
$\left.\begin{matrix}\alpha\\\beta\end{matrix}\right\}$ = $\alpha-\beta$ axes used in motor analysis

Assumptions

Fluid System

1. System pressure drop is assumed to be a function of flow only.
2. Steady-state pump characteristics are assumed to hold even though the flow is transient.
3. It is assumed that the fluid is incompressible and that there is no loss of fluid from the system.
4. Thermal effects, both transient and steady-state, are neglected.
5. It is assumed that the constants of the two loops are the same.

Motors

1. Balanced rotor and stator windings are assumed.
2. It is assumed that the coefficient of mutual inductance between any stator winding and any rotor winding is a cosinusoidal function of the electrical angle between the axes of the two windings.
3. It is assumed that the rotor is smooth and that the self-inductances of all the windings are independent of rotor position.
4. The effects of saturation, hysteresis, and eddy currents are neglected.
5. The effects of transient stator currents are neglected.

Appendix II. Fluid System Equations

Development of General Equations

The dynamical equations which describe transient flow in a fluid system are easily derived, in the 1-dimensional case, by equating net power input to the rate of change of fluid kinetic energy. In the multiloop case, however, it is easier to apply the equations of Lagrange:

$$\frac{d}{dt}\frac{\partial T}{\partial \dot{q}_i}-\frac{\partial}{\partial q_i}(T-U)=Q_i \tag{3}$$

where T, U, and Q_i are respectively the kinetic energy, the potential energy, and the generalized forces acting on the system. The $\dot{q}_i$ are generalized velocities and the q_i are generalized displacements. Since the fluid is incompressible and body forces are not considered, the potential energy term may be omitted.

In a series of lengths of pipe, each of constant cross section, the kinetic energy may be expressed as follows:

$$KE=\sum\frac{1}{2}mv^2$$

$$=\frac{1}{2g}(W_1v_1^2+W_2v_2^2+\ldots)=\frac{1}{2g}\sum W_jv_j^2 \tag{4}$$

Now, since

$$W_j=A_jl_j\rho \tag{5}$$

and

$$v_j=\frac{W}{A_j\rho} \tag{6}$$

then

$$KE=\frac{W^2}{2g\rho}\sum l_j/A_j \tag{7}$$

In a multiloop system, the total kinetic energy is the sum of the fluid energies in the various flow paths.

The partial derivative of the kinetic energy with respect to displacement is zero; the derivative with respect to velocity is obtained as follows:

$$\frac{\partial}{\partial v_j}(KE)=\frac{\partial}{\partial v_j}\frac{(A_j\rho v_j)^2}{2g\rho}\sum l_j/A_j$$

$$=\frac{A_j^2\rho v_j}{g}\sum \Sigma l_j/A_j \tag{8}$$

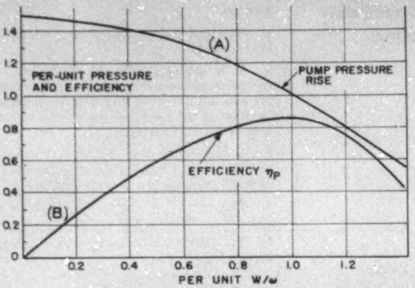

Fig. 8. Typical characteristics of single-suction radial flow centrifugal pump

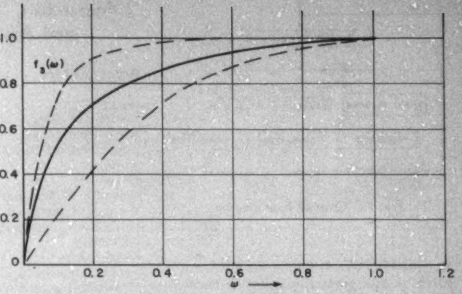

Fig. 9. Variation of design point impeller efficiency with speed

The force acting on the area A_j is simply $A_j\Delta P_i$, where ΔP_i is the net pressure rise around the flow path. The Lagrange equations then give, for a 2-loop system, the following:

$$\frac{A_j{}^2\rho}{g}\frac{dv_j}{dt}\sum l_j/A_{ji}=A_j\Delta P_i \qquad i=1,2$$

or

$$\frac{\sum l_1 A_{j1}}{g}\frac{dW_1}{dt}+\frac{\sum l_j/A_{jR}}{g}\frac{d(W_1+W_2)}{dt}=\Delta P_1 \tag{9}$$

$$\frac{\sum l_j/A_{j2}}{g}\frac{dW_2}{dt}+\frac{\sum l_j/A_{jR}}{g}\frac{d(W_1+W_2)}{dt}=\Delta P_2$$

in which the subscripts 1, 2, and R indicate respectively loop 1, loop 2, and the portion of the flow path common to both loops.

Equations 9 now permit the calculation of the flow derivatives in terms of the pump pressure heads and the frictional pressure drops in the two loops.

Steam Pressure Rise

The net pressure rise is the difference between the pressure head produced by the pump and the frictional pressure drop caused by the instantaneous flow. The pressure head developed by the pump is developed from the following general affinity relations:

$$\frac{\Delta P_P}{\omega^2}=f_1\left(\frac{W}{\omega}\right) \tag{10}$$

The function f_1 is evaluated from a steady-state head-capacity characteristic at a known speed, and then ΔP_P can be formed for any flow and speed. A typical pump characteristic is shown in Fig. 8(A).

The frictional pressure drop is a function of flow only, with the major part generally of the form

$$\Delta P=K(W)^{\alpha} \tag{11}$$

The exponent α is commonly taken as 2, but may vary downward to 1.9 or lower, depending on system configuration. The results shown in this paper were obtained using a tabulated function shown in Table I.

A part of the frictional pressure drop may occur in a valve or other special element in the flow path, and this drop may be a function of flow more complicated than can be described by equation 11. In this study, the pressure drop in a check valve is included as part of the function in Table I.

It is important to recognize that, in a multiloop problem, components of the frictional pressure drop occur in portions of the flow path common to two or more loops. These drops must be evaluated separately, with the use of total flow in equation 11. A value $\alpha=2$ was used to calculate this component of pressure drop.

Impeller Efficiency

The mechanical torque acting on the pump motor may be found from the expression

$$T_M=\frac{\Delta P_P W}{\omega\eta_P}+K_W\omega^2 \tag{12}$$

which expresses impeller losses in terms of an efficiency η_P and includes rotor friction and windage as a function of speed. The efficiency is calculated as a product of two functions:

$$\eta_P=f_2\left(\frac{W}{\omega}\right)\ f_3(\omega) \tag{13}$$

The first function $f_2\ (W/\omega)$ expresses the relation between efficiency and relative flow rate. At a given speed, the efficiency is zero at zero flow, and reaches a maximum at some known value of flow. At design speed, the flow for maximum efficiency is the design point flow. This function is based on test data, and is shown in Fig. 8(B). Since test curves of this function on pumps of various designs do not vary appreciably, it may be considered reliable.

The second function, $f_3(\omega)$ expresses the reduction in maximum efficiency from the design point value at speeds other than rated speed. This function is also based on test data, but there is considerable variation in these data from one pump design to the next, so that this function should be selected with care. The function used in this study is shown in Fig. 9, with a typical range of variation shown in dashed lines. The evaluation of rotor friction and windage is discussed in Appendix III.

Appendix III. Motor Equations

Mechanical Losses

The motor friction and windage torque is assumed to be proportional to the square of speed, the constant of proportionality being derived from dimensional analysis and empirical data.

Fundamentally

$$\text{Power loss}=K\omega^3D^4L \tag{14}$$

For a given motor and pump, K can be determined by test and D and L are fixed; therefore equation 14 can be simplified:

$$\text{Power loss}=K^1\omega^3$$

and finally

$$T_{\text{windage}}=K_W\omega^2 \tag{15}$$

Currents, Torques, Flux Linkages, and Acceleration

The following equations, used for the calculation of motor quantities, are derived in reference 4, under the assumptions listed in Appendix I. The relations are the same for both motors, so the 1 and 2 subscripts are omitted.

$$I_\alpha=\frac{1}{X}\left(E_\beta-\frac{M}{L_r}\psi_\alpha\right) \tag{16}$$

$$I_\beta=\frac{1}{X}\left(-E_\alpha-\frac{M}{L_r}\psi_\beta\right) \tag{16A}$$

$$T_E=\frac{M}{L_r}(\psi_\alpha I_\beta-\psi_\beta I_\alpha) \tag{16B}$$

$$p\psi_\alpha=-\frac{r}{L_r}\psi_\alpha-\psi_\beta p\theta+\frac{r}{L_r}MI_\alpha \tag{16C}$$

$$p\psi_\beta=-\frac{r}{L_r}\psi_\beta+\psi_\alpha p\theta+\frac{r}{L_r}MI_\beta \tag{16D}$$

$$p\omega=\frac{1}{2H_M}(T_E-T_M) \tag{16E}$$

Equations 16 through 16(E) are general (though approximate) but must be modified for use in specific cases. For the case in which the motor breakers are assumed to open, zero current is forced by setting $1/X=0$ in equations 16 and 16(A). When this is done, the electrical torque computed from equation 16(B) will be zero also. With standard types of induction motors, during an open-circuit coastdown from rated conditions, the electrical torque developed would indeed be negligible, because the open-circuit core loss would be very small. However, with the "canned" motors used in reactor coolant pump applications, the rotor is coupled to a dissipative circuit even though the stator is open, and the power loss in this circuit must be supplied through an electrical torque which acts with the mechanical load to decelerate the rotor. The following equation is used to compute this torque for open-circuit cases.

$$T_{E(oc)}=-\frac{1}{R_M}\left(\frac{M}{L_r}\right)^2\omega(\psi_\alpha^2+\psi_\beta^2) \tag{17}$$

This equation can be derived easily from the common steady-state equivalent circuit of an induction motor.

In equations 16 through 16(E), E_α and E_β are the 2-phase components of applied voltage, and in normal operation $E_\alpha=1.0$, $E_\beta=0$. For the loss of excitation case, illustrated by Fig. 4, the constant value for E_α is replaced by a value computed from the following equation.[7]

$$E_\alpha=1.0\epsilon^{-t/T_{ds}'} \tag{18}$$

where

$$T_{ds}'=T_{do}'\frac{(X_d'+X_e)(X_q+X_e)+(r+r_e)^2}{(X_d+X_e)(X_q+X_e)+(r+r_e)^2} \tag{18A}$$

Reference 7 defines the quantities used in this equation.

Appendix IV. Complete System Equations

In this Appendix, the complete set of equations for the system will be listed. The flow diagram of Fig. 5 shows the sequence of calculations. The pump pressure rise is calculated with the use of the relationship given in equation 19, solved for ΔP_p:

$$\Delta P_p=\omega_N{}^2 f_1\left(\frac{W}{\omega}\right) \tag{19}$$

The function $f_1(W/\omega)$ is stored in the computer in tabular form. For use in this calculation, the impeller speed is normalized:

$$\omega_N=\omega/\omega_0 \tag{20}$$

where ω_0 is rated impeller speed.

Next, the loop pressure drops are computed:

$$\Delta P_{L1}=K_{L1}g_1(W_1) \tag{21}$$

$$\Delta P_{L2}=K_{L2}g_1(W_2) \tag{21A}$$

where $g_1(W)$ is the function given in Table I. Note that this function is normalized: $g_1(1.0)=1.0$. The constants K_{L1} and K_{L2} are introduced to give the correct per-unit loop pressure drop at unit flow.

The reactor pressure drop is computed from

$$\Delta P_R=K_R(W_1+W_2)^2 \tag{22}$$

The next step is the calculation of the flow derivatives. If, in equation 9, the terms of the form $(\Sigma l/A)/g$ are replaced by inertia factors $2H$, the results are

$$2H_{L1}\frac{dW_1}{dt}+2H_R\frac{d(W_1+W_2)}{dt}=\Delta P_1$$

$$2H_{L2}\frac{dW_2}{dt}+2H_r\frac{d(W_1+W_2)}{dt}=\Delta P_2$$

and, solving for the derivatives with $H_{L2}=H_{L1}=H_L$, yields

$$\begin{aligned}\frac{dW_1}{dt}&=A\Delta P_1-B\Delta P_2\\&=A(\Delta P_{P1}-\Delta P_{L1}-\Delta P_R)-\\&\qquad B(\Delta P_{P2}-\Delta P_{L2}-\Delta P_R)\end{aligned} \tag{23}$$

$$\begin{aligned}\frac{dW_2}{dt}&=A\Delta P_2-B\Delta P_1\\&=A(\Delta P_{P2}-\Delta P_{L2}-\Delta P_R)-\\&\qquad B(\Delta P_{P1}-\Delta P_{L1}-\Delta P_R)\end{aligned} \tag{23A}$$

in which

$$A=\frac{H_L+H_R}{2H_L(H_L+2H_R)} \tag{24}$$

$$B=\frac{H_R}{2H_L(H_L+2H_R)} \tag{24A}$$

Equations 23 and 23(A) are the ones used in the computer program to calculate flow derivatives.

The mechanical torque on the impeller shaft is computed next. Equations 12 and 13 are used; for T_{M1}

$$T_{M1}=\frac{(\Delta P_{P1})(W_1)}{(\omega_{N1})(\eta_{P1})}+K_W(\omega_{N1})^2 \tag{25}$$

$$\eta_{P1}=\left[f_2\left(\frac{W_1}{\omega_{N1}}\right)\right][f_3(\omega_{N1})] \tag{26}$$

The equations are the same for T_{M2} and η_{P2}.

The calculation of electrical quantities is next. The equations used are 16 through 16(E).

Appendix V. Calculation of System Constants

As is the case with many analytical studies, the determination of system constants for this problem is one of the most difficult phases of the study. There are two reasons for this. First, it is inherently difficult to obtain equipment performance data which will be valid for transient analysis. This is particularly true for the canned motors, which represent a departure from standardized designs. Second, in a composite system, the various items making up the system are supplied by different groups, and the analyst himself must often assume the responsibility for collecting data from several sources.

With respect to the difficulty of obtaining valid data, there is need to recognize that transient analyses of composite systems will be requested more and more frequently as control and protection arrangements become more complex. There appears to be a great need for standardized definitions of the quantities which become important in the study of transient motor phenomena.

In analyzing system problems, it is useful to express the important variables as decimal fractions of a specified reference value, in other words, in per unit (pu). When this is done, all the dimensional constants in the problem must be modified so that the system equations are satisfied when pu values are used throughout. Although this modification may require considerable calculation, it has advantages which make the preliminary work worth while. First, an evaluation of system performance in pu permits easy comparison with other systems of the same general type but of different sizes. An important consequence of this kind of comparison is the likelihood that errors will be detected, whether they occur in system parameters or in the results. A second important advantage is obtained if the calculations are made with automatic computing equipment, either analog or digital, for the expression of quantities in pu accomplishes all or nearly all of the scaling which is often required in the application of this equipment.

The first step in converting system data to pu is the selection of base quantities. It is common to select a power base, a time base, and a base value for one other quantity. These selections are sufficient to determine all other quantities; the selection of additional base quantities will lead to inconsistency. In this study of 2-loop flow transients, it was decided to use as base power the hydraulic power at rated flow, one second as base time, and rated flow as base flow. Since hydraulic power (HP)=(W)(ΔP), this selection also makes rated pressure drop correspond to base or unit pressure drop.

The evaluation of system constants in pu is shown in the following for a typical set of basic data. The base quantities are:

Base flow = rated loop flow $=3\times10^6$ pounds per hour
Base pressure drop = rated pump head = 130.6 psi (pounds per square inch)
Fluid density = 47.74 pounds/ft (per foot)

$$\text{Base power}=\frac{(W_{\text{base}})(\Delta P_{\text{base}})(144)}{(\rho)(3{,}600)(550)}\text{ HP}$$

$$=\frac{(3\times10^6)(130.6)(144)}{(47.74)(3600)(550)}=$$

$$586.67\text{ HP}$$

$$=437.48\ K_W$$

The system pressure drops at full flow are given as follows:

Loop (not common to both loops), psi	59.3
Reactor (common to both loops), psi	71.3
Total	130.6

The pressure drop coefficients are therefore

$$K_L=\frac{59.3}{130.6}=0.45406$$

$$K_R=\frac{71.3}{130.6}\times\frac{1}{4}=0.54594\times\frac{1}{4}=0.13648$$

Next must be calculated the inertia factors in the flow derivative equations. To do this, return to equation 9 and observe that the numerical exactness of this equation must be preserved when the flow and pressure drop are expressed in pu. To see what this implies, multiply the left-hand side by W_B/W_B (base flow) and divide each term in the equation by ΔP_B:

$$\frac{\left(\sum l/A_1\right)W_B}{(g)\Delta P_B}\frac{d(W_1/W_B)}{dt}+\frac{\left(\sum l/A_R\right)W_B}{(g)\Delta P_B}\frac{d(W_1+W_2)/W_B}{dt}=\frac{\Delta P_1}{\Delta P_B}$$

Flow and speed are now in pu. Now, consider the coefficient of the first flow derivative term. Multiply this coefficient by a unity ratio, as follows:

$$\frac{2\rho W_B}{2\rho W_B}\frac{\left(\sum l/A_1\right)W_B}{(g)\Delta P_B}=\frac{2\dfrac{\left(\sum l/A_1\right)W_B^2}{2g\rho}}{\dfrac{W_B\Delta P_B}{\rho}}$$

This manipulation, together with equation 7 and the expression for base power just given, show that this flow derivative coefficient is equal to twice the ratio of the loop fluid kinetic energy to the hydraulic power at rated flow, i.e.,

$$H_L=\frac{KE_{\text{loop}}}{\text{base power}}\text{ (in compatible units)}$$

Similarly, it can be shown that

$$H_R=\frac{KE_{\text{reactor}}}{\text{base power}}$$

These two relations make the calculation of the inertia coefficients simple, and provide a useful physical picture. The numerical calculation follows:

Fluid inertias (given)

$$\Sigma l/A_{\text{total/loop}}=200.5\text{ ft}^{-1}$$

$$\Sigma l/A_{\text{reactor}}=5\text{ ft}^{-1}$$

$$\Sigma l/A_{\text{loop}}=200.5-2\times5=190.5\text{ ft}^{-1}$$

Stored energy at full flow

$$KE_{\text{loop}}=\frac{(190.5)(3\times10^6)^2}{(2)(3600)^2(48.57)(32.2)(550)}$$

$$=76.8975\text{ hp-sec (seconds)}$$

$$KE_{\text{reactor}}=\frac{(5)(2\times3\times10^6)^2}{(2)(3600)^2(48.57)(32.2)(550)}$$

$$=8.07323\text{ hp-sec}$$

$$H_{\text{loop}}=\frac{76.8975}{586.67}=0.13107\text{ sec}$$

$$H_{\text{reactor}}=\frac{8.07323}{586.67}=0.013761\text{ sec}$$

These inertia factors have the dimensions of time. A useful physical check exists in the fact that a time equal to $2H$ is required for the inertia thus described to experience a change in speed (flow) equal to base speed (flow) when base force (pressure) is uniformly applied.

Now, A and B are as follows:

$$A=\frac{H_L+H_R}{2H_L(H_L+2H_R)}=3.4837\frac{1}{\text{sec}}$$

$$B=\frac{H_R}{2H_L(H_L+2H_R)}=0.33101\frac{1}{\text{sec}}$$

A similar analysis shows that the H_M of equation 16(E) can be calculated with the use of the kinetic energy of the impeller and rotor:

$$KE_M=\frac{1}{2}J\omega^2=\frac{(95.5)(377)^2}{(2)(32.2)(550)}$$

$$=383.211\text{ hp-sec}$$

In this case, the quantity given is the motor and impeller $WK^2=95.5$ pounds/ft². Then

$$H_M=\frac{383.211}{586.67}=0.65320\text{ sec}$$

It should be pointed out here that the pu representation of system inertias, using H-factors, makes clear the important fact that most of the system inertia resides in the rotors and impellers of the pumps. In such a system including both fluid and rigid-body inertia, the use of common physical units might obscure this point.

Next is calculated the constant K_W associated with rotor friction and windage loss. Preliminary calculations give the power loss due to friction and windage as

$$P=6.12\times10^{-4}\omega^3\text{ ft-pounds/sec}$$

where ω is given in radians/sec.

The pu power at rated speed is therefore

$$P=\frac{(6.12\times10^{-4})(377)^3}{(550)(586.67)}=0.10163\text{ per unit}$$

Since power equals the product of torque and speed, and rated speed = 1.0 in pu:

$$K_W=0.10163$$

The calculation of motor constants is usually made, and these constants are given, using the motor output rating as a pu base. These values must be modified to put them in pu on the hydraulic power base. The ratio of the bases can be found by calculating the motor power (or torque at unit speed) required to give unit hydraulic power.

$$(T_M)(\omega)=\frac{(W_B)(\Delta P_B)}{(\omega)(\eta_p)}\omega+K_W\omega^2\omega$$

$$=\frac{(1.0)(1.0)}{(1.0)(0.83)}(1.0)+(0.10163)(1.0)^2(1.0)$$

$$=1.306\text{ pu}$$

Therefore, the motor output should be 1.306 pu to give unit hydraulic power.

The motor constants used for this study were obtained partly from design data and partly on the basis of assumed similarity with other similar motors for which complete data were available. The values used are listed in Table II.

The numerical values used in the loss of excitation case are as follows:

$X_d=1.300$
$X_d'=0.210$
$X_q=0.900$
$r=0.005$ (approximately)
$T_{d0}'=3$ sec
$T_{dz}'=1.682$ sec
$X_e=0.456$
$r_e=0.989$

Note that X_e and r_e are calculated on the assumption of an average load of 0.9 pu kilovolt-amperes (on the generator base) at 0.89 power factor.

Appendix VI. Features of Numerical Integration Subroutine

As pointed out in the "Outline of Analysis and Computer Programming," the numerical manipulations required in the application of equations 2 and 2(A) can be programmed in the form of a subroutine for general use.

The accuracy obtainable in a solution using equations 2 and 2(A), or other such equations corresponding to other methods of numerical integration, is limited by the error in the calculation made at each step. In general, these components of error are cumulative. The error per step results from two causes: round-off error, which depends on the number of significant figures maintained in the computation, and truncation error, which results from the fact that the integration is performed over finite rather

Table II. Pump Motor Constants in PU

Constant	On Motor Base	On Hydraulic Power Base
x	0.1150	0.08804
M	2.775	2.1243
L_r	2.819	2.1584
r	0.00445	0.00341
R_M	13.06	10.00

than infinitesimal intervals. For a given set of integrating equations, the truncation error per step depends on the length of the integrating interval.

The length of the integrating interval therefore affects over-all accuracy in two ways. A change in this interval changes the truncation error per step, and also changes the number of steps required to complete a given solution, which affects the amount of accumulation of both types of error. Thus the selection of the integrating interval is an important decision with regard to the accuracy of the solution, and there is at least an indication that there may be an optimum interval for a given problem, in the sense that either increasing or decreasing the interval from this value will increase the over-all error. The selection of the interval is also an economic decision, since the time required to compute a step is the same whether the step is a long or a short one.

From the point of view of both over-all accuracy and economics, it is desirable to maintain uniform error per step throughout a solution, and this can be achieved only by allowing the interval to change during the process. If a numerical solution were to be obtained by hand, this control over the interval would be simple. If a digital computer is to be used, the control must be automatic; i.e., the decision to change the interval must be made by the computer.

The subroutine which was used to obtain the results shown in this paper incorporates an automatic estimate of the truncation error at each step, and it is able to make a change in the interval (doubling or halving) if the estimated error falls outside a specified range.

The operation of the error-estimating portion of the program is as follows. The program first compares the estimated error in a selected variable with the maximum allowable error. If the error is too large, the program goes back to the next previous set of *y*-values, halves the integrating interval, and tries again until the error is below the upper limit.

If the error is below the upper limit, the program next compares it with the minimum economic error. If it is greater than the minimum, the program goes ahead to the next interval. If the error is less than the minimum, the program goes ahead but it starts a counter as it does so. If the error is less than the minimum at each step for five successive steps, the calculation proceeds with a doubled integrating interval. The counter is returned to zero at every step unless the error is less than the minimum, so the count does not accumulate unless the low-error calculations occur in succession. The demand for five successive low-error calculations is arbitrary, and a lower or higher number can be used if it seems desirable.

Transistor Phase-Locked Oscillators

K. A. EDWARDS
NONMEMBER AIEE

O. GOLUBJATNIKOV
NONMEMBER AIEE

D. J. BRADY
NONMEMBER AIEE

THE USE of phase-locked oscillator control loops for the detection and tracking of signals in the presence of noise is well known and has been extensively analyzed.[1-4] Two completely transistorized phase-locked oscillator systems have been developed which perform these functions. System I operates at an input center frequency of 10.5 kc, and system II operates at 30 megacycles.

An additional function of frequency multiplication is obtained in the first of the two systems described by the addition of a frequency divider in the feedback path from the oscillator to the phase detector. This permits small input frequency shifts to be readily measured with a frequency counter. This basic system was suggested by Dr. L. J. Neelands.

The systems described have been designed for two different applications. In both systems, considerable advantage is obtained by use of transistors and semiconductor diodes. Some features peculiar to the systems described here, which result from the use of solid-state devices, are outlined as follows and will be described in detail later:

1. In order to obtain a narrow noise bandwidth, a long-time-constant integrating network is necessary. A simple *R-C* network is not suitable due to the lower impedance levels of transistor circuitry. A feedback integrator is used, and an analysis of the control loop stability including the effects of the integrator is shown.

2. The narrow bandwidth causes difficulty in locking on a signal during the search mode. This problem is solved with a nonlinear network in the integrator.

3. The phase detector permits use of the switching properties of transistors in a simple and reliable circuit. A signal is also provided for a novel phase-lock indicator.

4. A unijunction transistor provides a simple means of generating a search signal.

5. The freedom of transistors from microphonics and hum permits the elimination of a derivative feedback loop found necessary on comparable vacuum-tube equipment.

Linear Analysis

This analysis is based primarily on the transfer functions of system I; see Fig. 1. It includes the effects of the feedback frequency divider and feedback integrator. The equations apply to system II also; however, for system II, the frequency divider ratio M is unity and the feedback term $K_2(\tau_1-\tau_2)$ in the time constant τ_2 is zero.

The following simplifying assumptions are made in the analysis:

1. The phase detector output is a linear function of the phase difference between the feedback and reference inputs.

2. Leakage of the feedback capacitor and shunting effect of the amplifier input are neglected.

3. The amplifier output impedance is included in the time constant τ_2.

4. The oscillator control current and frequency are assumed to be linear functions of the amplifier feedback voltage.

5. Time constants of the oscillator control coil and the phase detector filter are neglected.

Paper 58-1276, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31 1958. Manuscript submitted April 9, 1958; made available for printing September 5, 1958.

K. A. EDWARDS and O. GOLUBJATNIKOV are with the General Electric Company, Syracuse, N. Y., and D. J. BRADY is with United Engineers, Inc., Boston, Mass.

Credit is due D. L. Hagen of the General Electric Advanced Engineering Program for his contributions to the analysis of system I and for the development of the lock indicator and search circuit. J. T. Holland, Jr., suggested the method of injecting the search signal in system I. Dr. L. J. Neelands gave assistance with determining the system requirements and with the analysis. F. J. Ryan and W. R. McKinley contributed much experimental work and refinements of the circuits.

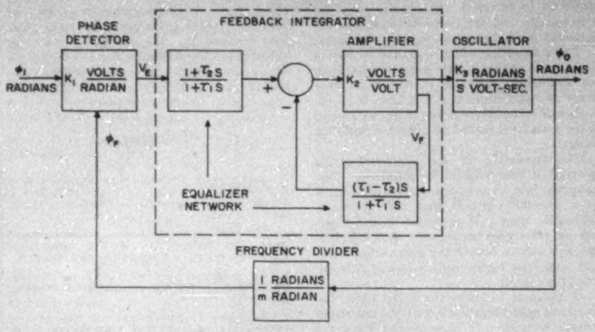

Fig. 1. Transfer functions of system I

Referring to Fig. 1, the transfer function of the feedback integrator v_F/v_E as a function of the Laplace operator S is

$$\frac{V_F}{V_E}(S)=\frac{K_2(1+\tau_2 S)}{1+[K_2(\tau_1-\tau_2)+\tau_1]S} \tag{1}$$

where τ terms are time constants and K terms are gains.

The open-loop gain of the phase lock system is

$$G(S)=\frac{K_1K_2K_3}{M}\left\{\frac{1+\tau_2 S}{1+[K_2(\tau_1-\tau_2)+\tau_1]S}\right\}\left\{\frac{1}{S}\right\} \tag{2}$$

where M is the frequency division ratio.

The closed-loop transfer function is

$$\frac{\phi_0}{\phi_1}(S)=\frac{M\left(\frac{K}{T_3}\right)(1+\tau_2 S)}{S^2+\left(\frac{1+K\tau_2}{\tau_3}\right)S+\frac{K}{\tau_3}} \tag{3}$$

where ϕ terms are phase angles in radians and

$$\tau_3=K_2(\tau_1-\tau_2)+\tau_1$$

$$K=\frac{K_1K_2K_3}{M}$$

From servomechanism convention, equation 3 can be written,[5]

$$\frac{\phi_0}{\phi_1}(S)=\frac{M\left[\omega_n^2+\left(2\zeta\omega_n-\frac{\omega_n^2}{K}\right)S\right]}{S^2+2\zeta\omega_n S+\omega_n^2} \tag{4}$$

where

ζ = ratio of actual to critical damping
ω_n = resonant frequency of loop

It is seen that

$$\omega_n=\sqrt{\frac{K}{\tau_3}} \tag{5}$$

$$2\zeta\omega_n=\frac{1+K\tau_2}{\tau_3} \tag{6}$$

$$\frac{2\zeta}{\omega_n}=\frac{1}{K}+\tau_2$$

$$\zeta=\frac{\omega_n}{2K}+\frac{\tau_2\omega_n}{2}$$

For most cases,

$$\tau_2\omega_n>>\frac{\omega_n}{K}$$

$$\zeta\approx\frac{\tau_2\omega_n}{2} \tag{7}$$

NOISE BANDWIDTH

The noise bandwidth may be obtained by evaluating the integral,

$$B=\int_{-\infty}^{+\infty}\left|\frac{\phi_0}{\phi_1}(j\omega)\right|^2 d\omega \tag{8}$$

Equation 4 in terms of $j\omega$ becomes

$$\frac{\phi_0}{\phi_1}(j\omega)=\frac{1+j2\zeta\frac{\omega}{\omega_n}\left(1-\frac{\omega_n}{2\zeta K}\right)}{1+j2\zeta\frac{\omega}{\omega_n}-\left(\frac{\omega}{\omega_n}\right)^2}M \tag{9}$$

Substituting equation 9 in 8,

$$B=M^2\omega_n\times$$

$$\int_{-\infty}^{+\infty}\frac{1+4\zeta^2\left(\frac{\omega}{\omega_n}\right)^2\left(1-\frac{\omega_n}{2\zeta K}\right)}{1-(2-4\zeta^2)\left(\frac{\omega}{\omega_n}\right)^2-\left(\frac{\omega}{\omega_n}\right)^4}d\frac{\omega}{\omega_n} \tag{10}$$

The integration of an equation of this form was done by Gruen[1] with the following result:

$$B=M^2\pi\omega_n\frac{4\zeta^2-4\zeta\frac{\omega_n}{K}+\left(\frac{\omega_n}{K}\right)^2+1}{2\zeta} \tag{11}$$

For

$$\frac{\omega_n}{K}\rightarrow 0$$

and in terms of input bandwidth,

$$\frac{B}{M^2}=\pi\omega_n\frac{4\zeta^2+1}{2\zeta} \tag{12}$$

Ingham[8] has shown that B is minimum for $\zeta=0.5$. Fig. 2 shows a calculated curve of B/M^2 as a function of ζ.

HOLD-IN RANGE

Gruen has analyzed hold-in range for a linear system where the phase detector output is proportional to the sine of the phase difference.[1] In the system under consideration, the phase detector output is directly proportional to the phase difference over a wide range. An analysis of linear effects follows.

In order to keep the equations in terms of the input frequency, ϕ_0/M rather than ϕ_0 will be used.

$$\phi=\phi_1-\frac{\phi_0}{M} \tag{13}$$

From equation 4,

$$\frac{\phi_0}{M}=\frac{\omega_n^2+\left(2\zeta\omega_n-\frac{\omega_n^2}{K}\right)S}{S^2+2\zeta\omega_n S+\omega_n^2}\phi_1 \tag{4}$$

Combining equations 4 and 13

$$(S^2+2\zeta\omega_n S+\omega_n^2)\phi=\left(S^2+\frac{\omega_n^2}{K}S\right)\phi_1 \tag{14}$$

If the difference between the input and feedback frequency $\Delta\omega=s\phi_1$ is a constant, equation 14 becomes

$$(S^2+2\zeta\omega_n S+\omega_n^2)\phi=\frac{\omega_n^2}{K}\Delta\omega \tag{15}$$

The steady-state solution is

$$\phi=\frac{\Delta\omega}{K} \tag{16}$$

$$\therefore\ \Delta\omega_{\text{hold-in}}=K\phi_{\max} \tag{17}$$

The maximum excursion of ϕ is determined by the saturation of the amplifier and oscillator control characteristics once the phase detector characteristic is known.

Description of System I

that initially the system is not phase-locked. A d-c signal from the phase detector causes the lock indicator to de-energize the relay thus giving a no-lock indication and connecting the search multivibrator to the output stage of the d-c amplifier.

As the multivibrator waveform swings positive, the oscillator frequency goes to its lowest value in less than 1 second. The rapid retrace is due to *CR-3* switching to the conducting state, permitting rapid discharge of capacitor *C*. As the multivibrator swings negative, *CR-3* ceases to conduct, and the waveform is integrated to produce a sawtooth of current in the oscillator control coil which sweeps the oscillator frequency slowly toward its upper frequency limit.

The bandwidth of the system is increased during the search and pull-in by the conduction of *CR-1* or *CR-2* which switches shunting resistance across R_1 to reduce the integrator time constant.

When the oscillator frequency reaches a value such that the frequency divider output equals $f_0 \pm \Delta f$, the system pulls into synchronism. The phase detector output then goes to its locked-in range of voltage. This causes the lock indicator to energize the relay, disconnecting the search multivibrator, and returning the d-c amplifier to the power supply. The oscillator output is then $64f_0 \pm 256\Delta f$.

The clock frequency is synchronized with the input frequency f_0. When incoming intelligence is received, f_0 is shifted by Δf, but the clock frequency does not shift. Thus, the Δf is multiplied by 256, but f_0 is only multiplied by 64. The magnitude of Δf is proportional to the magnitude of the intelligence.

The frequency multiplication feature permits the Δf to be determined to a greater accuracy in a shorter sampling time using a frequency counter.

Calculation of System I Constants

The following performance for the phase-locked loop was set as a goal:

1. Noise bandwidth ≤ 50 cps (cycles per second) or 314 rad/sec (radians per second).
2. Search and pull-in time = <5 sec.
3. Hold-in range = 1,000 cps or 6,280 rad/sec.
4. Divider ratio $M = 256$.

The open-loop gain may be calculated from

$$K=\frac{\Delta\omega_{\text{hold-in}}}{\phi_{\max}} \qquad (17)$$

$\phi_{\max}$ is set at 0.5 rad to insure small-signal operation of the phase detector.

$$K=12{,}560 \text{ per sec} \qquad (18)$$

The loop resonant frequency may be calculated from

$$\omega_n=\left(\frac{B}{\pi M^2}\right)\left(\frac{2\zeta}{4\zeta^2+1}\right) \qquad (12)$$

Ingham[3] has shown that the maximum pull-range for a given noise bandwidth occurs at $\zeta=\sqrt{3}/2$. However, to insure stability with age and parameter variations, the damping factor ζ is made unity.

$$\omega_n=40 \text{ rad/sec} \qquad (19)$$

The time constant τ_1 is

$$\tau_1=\frac{K}{\omega_n^2} \qquad (5)$$

For $\omega_n \leq 40$ rad/sec

$$\tau_1 \geq 7.9 \text{ sec} \qquad (20)$$

The time constant τ_2 is

$$\tau_2 \approx \frac{2\zeta}{\omega_n} \qquad (7)$$

$$\tau_2 \approx 0.05 \text{ sec} \qquad (21)$$

Fig. 4. Nonlinear integrator

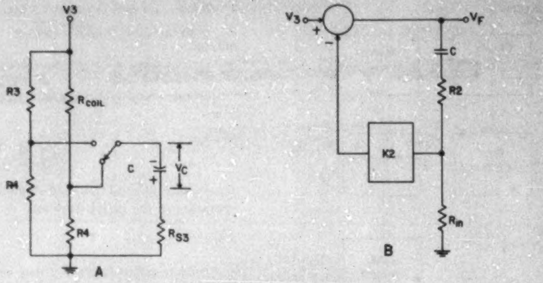

Fig. 5. Nonlinear integrator equivalent circuits

1. When the system is phase-locked, all diodes are nonconducting and linear analysis applies.
2. During the retrace of the search multivibrator (positive swing), *CR-3* conducts and discharges capacitor *C*.
3. During the search (negative swing) diode *CR-1* conducts shunting R_1 with R_{s1}, thus increasing the resonant frequency ω_n of the feedback loop. With a signal present, the phase detector output is positive, thus transistor Q_4 is cut off.
4. When the system is locked, sudden changes in phase detector output, if of great enough magnitude, will produce a drop across R_1 due to the charging current of capacitor *C*, sufficient to produce conduction of silicon junction diodes *CR-1* or *CR-2*. The bandwidth and damping factor are both increased, thus reducing the chance of unlocking due to spurious disturbances. The lock-in range for a given search time also increases.

The retrace time may be calculated from the equivalent circuit of Fig. 5(A). The diodes and transistors involved are assumed to be perfect switches, and shunting effects of the amplifier input circuitry are neglected.

During retrace *Q3* and *Q4* are cut off, and the base to emitter junction of *Q5* is conducting. The circuit may then be shown with the switch in the upper position in Fig. 5(A).

The time constant for the retrace τ_R is

$$\tau_R = \left(R_{S3} + \frac{R_3 R_4}{R_3 + R_4} \right) C \tag{22}$$

The time for the retrace transient to reach 90 per cent of steady state is

$$T_{Rm} = \tau_R \ln 10 \tag{23}$$

Starting from the retrace condition, assume a step function applied to the base of *Q6*. As normal transistor action is restored, the step function is integrated to produce as exponential increase of the feedback voltage V_F. The control coil current for the oscillator is approximately V_F/R_4.

The maximum search time occurs for the case where the required oscillator frequency, and hence V_F is at its highest value. The equivalent circuit of Fig. 5(B) is used to calculate the maximum search time T_{sm}. Resistance R_1 is shunted by R_{s1} since the phase detector voltage is always positive, causing *CR-1* to conduct, when the system is not phase-locked, and a signal is present. Using ordinary linear transient analysis T_{sm} is

$$T_{SM} = -\tau_B \ln \left(\frac{1 - V_f/V_3}{1 - \tau_A/\tau_B} \right) \tag{24}$$

where

$\tau_A = (R_{in} + R_2)C$

$\tau_B = [R_2 + R_{in}(1 + K_2)]C$

$R_{in} = R_{\phi 2} + \dfrac{R_1 R_{s1}}{R_1 + R_{s1}}$

$R_{2\phi}$ = approximate internal resistance of the phase detector

Circuit Design of System I

PHASE DETECTOR

The phase detector makes use of switching transistors and has some novel properties. Over a wide range, the output is very nearly a linear function of phase difference.

When the loop is not phase-locked, appropriate signals used to control a phase-lock indicator are obtained. A more detailed discussion of this circuit appears later in the paper.

NONLINEAR INTEGRATOR

Referring to Fig. 4, some considerations in the selection of circuit configuration and component values follow.

A single-stage voltage amplifier with feedback through an external emitter resistance for gain and operating point stability was chosen; the problem of feedback loop stability was thus eliminated. Emitter follower input and output stages were added for high input and low output impedances.

The magnitude of resistor of R_1 is limited by bias stability considerations; thus, a feedback integrator is needed to obtain the value of τ_3 indicated by the design calculations. To obtain the nonlinear operation, silicon junction diodes are used, due to the high forward voltage drop (approximately 0.5 volt) for *CR-1* and *CR-2*. Thus, the diodes are nonconducting even though slightly forward biased for normal linear operation. The values of resistors R_{s1} and R_{s2} were set experimentally for the best compromise between low noise bandwidth as determined by ω_n and short search time over the required range of frequencies for lock-in.

PHASE-LOCK INDICATOR

The phase detector properties are an important part of the operation of the phase-lock indicator. The phase detector d-c output voltage must be considered for three possible cases in the lock indicator operation; refer to Figs. 6 and 7. If the system is phase-locked, the phase detector voltage is in zone *A* (linear operation). The unlock indications are from zones *B* and *C*. The voltage in zone *B* only occurs when one of the signals is missing. If both signals appear, but the system is unlocked, the phase detector voltage jumps to the lower limit of zone *C*.

During unlock, the search multivibrator is connected to the nonlinear integrator; see Fig. 6. The search multivibrator generates an unsymmetrical square wave which gives a retrace time of approximately 0.4 sec and a search time of approximately 3 sec. The diodes limit the reverse voltage swing on the transistor bases to a safe value.

OSCILLATOR AND LINE DRIVER

The oscillator is a Colpitts circuit with frequency control through variation of the direct current in the control winding.

Since the required output from the system is a square wave, the oscillator drives a Schmitt trigger which supplies a square wave. The Schmitt trigger output drives the frequency divider and two emitter followers coupled through pulse transformers to four 75-ohm coaxial cables. The square wave output pulse to each of the cables is 2.5 volts peak-to-peak amplitude with a rise time of less than

0.2 microsecond. The frequency range is approximately 400 to 900 kc.

The Schmitt trigger also drives the frequency divider which consists of cascaded Eccles-Jordan flip-flops. A mixer is used to inject the clock frequency.

Description of System II

Fig. 8 shows a block diagram of the second phase-locked system which operates as follows: Assume that initially the loop is not phase-locked. The unijunction transistor sawtooth generator produces a sweep signal which is applied at the base of the control transistor sweeping the frequency of the saturable reactor controlled oscillator.

The output of this oscillator is mixed with a $f_0 \pm \Delta f$ signal from the receiver intermediate-frequency amplifier. Δf represents the desired intelligence and is masked by noise. The mixer output is amplified in a 455-kc narrow-band intermediate-frequency amplifier. A 6-kc bandwidth is achieved by the use of a magnetostriction filter. The foregoing signal and a signal from a crystal-controlled time-base oscillator are amplitude-limited and applied to a coincidence phase detector. As the mixer output varies in frequency, it will approach the frequency of the crystal reference, developing an error signal in the output of the phase detector. The frequency of the nominal f_0+f_c oscillator is shifted by the error voltage in such a direction as to reduce the error and the loop locks into synchronism.

When the loop is locked, the load impedance seen by the sweep generator is reduced in magnitude as compared to the unlocked case. This change in impedance level is sufficient to disable the unijunction sweep generator. A loop lock indication is obtained by applying the intermediate-frequency and time-base signals to a second coincidence phase detector which operates 90 degrees out of phase with the first phase detector. A Schmitt trigger circuit is used to activate the relay from the phase detector output.

When intelligence is being received f_0 is shifted by Δf. As the loop references frequency remains fixed, the loop readjusts itself and the intelligence Δf will add or subtract from the oscillator nominal frequency f_0+f_c. The output mixer following the oscillator strips the signal carrier frequency f_0 and leaves the intelligence with a bias frequency f_c to resolve directional ambiguities.

Calculation of System II Constants

The following performance was set as a goal for the 30-megacycle phase-locked loop:

1. Noise bandwidth, $B=5{,}000$ cps.
2. Search and pull-in time <5 sec.
3. Hold-in range, $\Delta\omega=10^6$ cps.

The following loop constants were computed from equations 5, 7, 12, and 17. ϕ_{max} was chosen as 0.5 rad and ζ was made unity.

$$K=1.26\times10^7/\text{sec} \tag{17}$$

$$\omega_n=4{,}000 \text{ rad/sec} \tag{12}$$

$$\tau_1=0.79 \text{ sec} \tag{5}$$

$$\tau_2=5\times10^{-4} \text{ sec} \tag{7}$$

Fig. 9. System II schematic

Circuit Design of System II

The circuit schematic of system II is shown in Fig. 9. Circuits which have been used in more than one location are repeated in block form. Coincident-phase-detector and unijunction-sweep-generator circuits are considered novel in this application and will be discussed in detail.

Phase Detector

Phase detectors may be constructed with only passive elements, such as diodes, but amplifiers are then usually required to make up for energy losses in the detector. A transistor phase detector combines the switching and amplifying properties of transistors and thus eliminates the need for additional amplifying stages.

A number of transistor-phase-detector circuits were investigated, including unijunction and symmetrical transistor[4] circuits. A coincidence phase detector was finally selected because of its simplicity, immunity to signal amplitude variations above a threshold, and linear characteristic. The circuit schematic and operating characteristics are shown in Fig 10.

Transistors Q_1 and Q_2 are series connected and both saturate if, and only if, both bases are simultaneously negative with respect to ground. If capacitor C is disconnected so that the waveform at the output may be examined, a series of square waves will be observed. If the signals are of the same frequency, the pulse width is determined by the phase difference of the two inputs. If the signals differ in frequency, a series of pulses of varying widths and repetition rates are produced. The addition of capacitor C produces a direct voltage proportional to the phase difference.

Transistor storage effects encountered during saturation seriously limit the maximum repetition rate at which the phase detector can be driven. Linearity of this circuit can be improved and driving rates increased by controlled saturation or preventing saturation by the use of a diode clamp or using nonlinear feedback.

The function of capacitor C_1 is to overdrive the transistor momentarily. Knowing the value of the stored base charge from the manufacturer's data, the value of the capacitor can be computed from the formula:

$$C_1 = \frac{Q_s}{E_1} \tag{25}$$

where

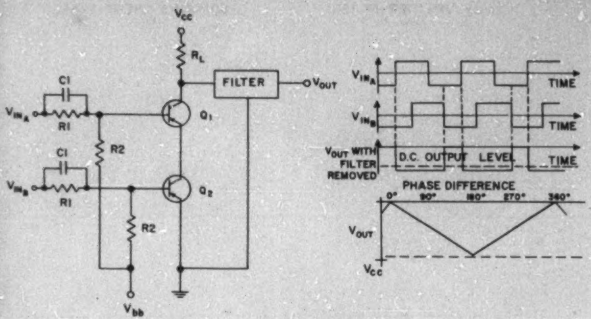

Fig. 10. Phase detector and operating characteristic

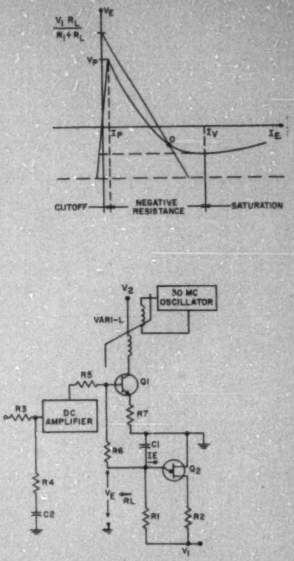

Fig. 11. Unijunction transistor sweep generator

C_1 = coupling capacitance, micromicrofarads
Q_S = stored base charge, micromicrocoulombs
E_s = input voltage, volts

The same result can be obtained experimentally by adjusting C_1 for minimum storage and fall time without an overshoot.

The value of R_1 is determined by the lower limit of h_{fe} of the transistors to be used. Bias voltage V_{bb} and resistor R_2 should be chosen so that the base potential will be slightly positive at the maximum temperature of operation.

There is a small delay due to the time it takes for the base to fall to ground potential. This delay is approximately equal for both channels resulting in a very small net effect. As the I_{co} of the transistor increases with temperature, the base becomes less positively biased, reducing the rise time. This effect is compensated by the decrease of the alpha-cutoff frequency due to decreased mobility of minority carriers.

SWEEP CIRCUIT

The negative-resistance characteristic of the unijunction transistor is utilized conveniently in a relaxation sawtooth oscillator to generate the necessary search signal. The circuit is shown in Fig. 11.

As the loop locks, the equivalent load resistance R_L seen by the sweep circuit is reduced in magnitude. The circuit must be designed so that it is monostable when the loop locks and is astable when the loop is unlocked. In terms of the operating characteristic, the load line of the R_1 and R_L parallel combination must intersect the V_p axis above the peak point V_p to assure that the diode will begin conducting during search. The load line must intersect below V_p when the loop is locked.

The intersection at point O must be in the negative resistance portion of the characteristic to ensure that the circuit begins to recharge the capacitor and does not operate at a stable point on the saturation portion of the curve. In the following expressions, it is assumed that $(R_L)NL > (R_L)L$ and that the base of Q_1 is approximately at ground potential.

During Search:

$$\left|\frac{V_1(R_L)NL}{R_1+(R_L)NL}\right| \geq |V_p| \tag{26}$$

and

$$\left|\frac{R_1(R_L)NL}{R_1+(R_L)NL}\right| \geq |R_{min}| \approx \left|\frac{V_p-V_v}{I_p-I_v}\right| \tag{27}$$

During Lock:

$$\left|\frac{V_1(R_L)L}{R_1+(R_L)L}\right| < |V_p| \tag{28}$$

Experimental Results

Table I shows experimental results. Calculated values where applicable were obtained from the relations derived earlier.

SYSTEM I

For determining the maximum Δf over which the system searched and locked on, the time base frequency f_e and the input frequency f_0 were set so that the mixer output was in the center of the pass band of the mixer output filter. The −3-decibel bandwidth of this filter is 150 kc, and the −30-decibel bandwidth is 230 kc with a center frequency of 672 kc. Thus, the frequency range is limited by the operating range of the d-c amplifier. The Δf realized is greater than the design objective which shows that the d-c amplifier has adequate operating range.

The design objective for the resonant frequency ω_n is determined by the desired noise bandwidth. A lower limit is im-

Search time < 5 sec	Search time = 2 sec		

posed by the maximum search time. The values of ω_n obtained indicate that the specifications have been met. The time constant τ_3 of the feedback integrator was measured with a Tektronix *535* oscilloscope. Phase difference measurements were made with the same oscilloscope and frequency measurements with a frequency counter. These measurements were made closed loop from which loop gains were determined at three different operating points. The variations in loop gain (and in ω_n) appear to be due to nonlinearity of the oscillator control coil in the lower range of oscillator frequency (upper range of $f_0 \pm \Delta f$) and to nonlinearity of the input current versus base to emitter voltage for the d-c amplifier transistors at the upper range of oscillator frequency.

The use of the nonlinear diode network permits the search time to be less than the design objective.

Since the phase detector gives limiting action, the theoretical performance of this system in the presence of random noise can be expected to follow the bandpass limiter case discussed by Jaffe and Rechtin.[7]

SYSTEM II

System II, with minor modifications, has been used to track signals in the 10- to 40-megacycle range. The sweep circuit described permits a Δf greater than ±500 kc. The ω_n with the circuit constants shown in Fig. 9 was measured at approximately 3,800 rad/sec which correlates well with the calculated value. The search rate is limited primarily by the passband characteristics of the 455-kc intermediate-frequency amplifier. The search time with the circuit constants shown is approximately 2 sec. At higher search rates, the lock-in reliability is reduced. Signal-to-noise ratios of approximately -10 decibels at the input from the receiver have been achieved.

Conclusions

The applicability of transistors to phase-locked oscillator control loops has been successfully demonstrated wth two systems operating in widely separated portions of the frequency spectrum. Also, the transistor circuitry is amenable to analysis. The use of nonlinear properties of semiconductor diodes and transistors permits seemingly conflicting objectives to be attained.

1957 Magnetic Amplifier Bibliography

AIEE COMMITTEE REPORT

THIS bibliography covers domestic and foreign literature for the year 1957. Some articles from the year 1956, not previously listed, are also included. The patents listed cover those issued between July 1956 and December 1957. Earlier magnetic amplifier literature is covered in a Magnetic Amplifier Applications Subcommittee report covering the literature for the years 1951 through 1956.[16]

The bibliography is divided into four major subdivisions as follows:

I. English Language Articles
II. Foreign Language Articles
III. Domestic Patents
IV. Foreign Patents

Within each major subdivision, papers and patents are classified according to subject matter as follows:

A. *Theory, Analysis, and Design*
Papers dealing primarily with the theory of operation of magnetic amplifiers, or with the analysis and design of circuits.

B. *Magnetic Regulation and Servo Applications*
Applications of magnetic amplifiers in the control of voltage, current, speed, temperature, frequency, position, etc.

C. *Magnetic Frequency Conversion*
Sub and ultraharmonic generators and magnetic frequency converters.

D. *Operational and Instrument Magnetic Amplifiers*
Metering and operational magnetic amplifiers and applications in analog computation. Magnetic modulators.

E. *Static Magnetic Switching Applications*
Digital computer applications and discrete step output magnetic amplifiers. Bistate magnetic amplifiers.

F. *Transistor-Magnetic Device Combinations*
All applications where transistors are used in conjunction with magnetic devices to provide new capabilities.

G. *Magnetism and Magnetic Materials*
Magnetic phenomena and the properties of magnetic amplifier materials.

H. *Measurements and Testing*
Techniques for the measurement of magnetic properties, core matching, and grading. Methods for measuring magnetic amplifier performance.

J. *Associated Devices*
Components used in conjunction with saturable reactors in magnetic amplifier circuitry. Devices generally associated with magnetic amplifier technique such as rectifiers, reference elements, etc.

K. *Ferroresonance and Its Applications*
The phenomenon of ferroresonance and its applications in regulation and harmonic frequency generation.

L. *Manufacturing Techniques, Environmental Effects, and Reliability*
Manufacturing and packaging techniques utilized to obtain a product reliable over a wide range of environmental conditions. The effects of radiation and temperature on magnetic amplifier performance.

Each subject heading is further subdivided into years. For each year, the papers under a given subject classification are listed alphabetically by author, except for patents which are listed in order of increasing patent numbers.

A list of abbreviations of the journals referred to in the bibliography and a list of general references on magnetic amplifiers follows.

Paper 58-1328, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Pittsburgh, Pa., October 26–31, 1958. Manuscript submitted August 7, 1958; made available for printing September 11, 1958.

The members of the Bibliography Working Group of the Applications Subcommittee of the AIEE Magnetic Amplifiers Committee are E. J. ALEXANDER, *chairman;* V. B. Boros, W. A. Geyger, R. B. Morgan, and R. A. Raber.

List of Journals and Their Abbreviations

AEG Mitt. (Berlin)	*AEG Mitteilungen.* Hohenzollerndamm 150, Berlin-Grunewald, Germany
AIEE Trans.	*Transactions*, American Institute of Electrical Engineers, 33 W. 39th Street, New York 18, N. Y. (*Communication and Electronics* is Part I of the *Transactions*)
ASEA J.	*ASEA Journal.* ASEA Electric Ltd., Fulbourne Road, London, E. 17, England; Allmänna Svenska Elektriska AB, Vasteräs, Sweden
Automation and Remote Control (USSR)	*Avtomatika i Telemekhanika.* Institute of Automatics and Telemechanics, Mowcow Center, Mal. Kharitonievsky, Per 4, Moscow, USSR
BTH Activ.	*BTH Activities.* British Thomson-Houston Company, Ltd., Rugby, England
Bull. Soc. Franc. Élect	*Bulletin*, Société Francaise des Électriciens, 8–14 Avenue Pierre Larousse, Malakoff, Seine, France
C. R. Acad. Sci (Paris)	*Comptes Rendus*, Hebdomadaires des Séances, Académie des Sciences, Libraire Gauthier-Villars, Quai des Grands-Augustins 55, Paris (6ᵉ), France
Cont. Engg.	*Control Engineering.* McGraw-Hill Publishing Company, 330 W. 42nd Street, New York 36, N. Y.
Direct Current	*Direct Current.* Garraway Ltd., 11A Kensington Church Street, London, W. 8, England
Dtsch. Electrotechnik	*Deutsche Electrotechnik.* Verlag Technik, Unter den Linden 12, Berlin, N.W. 7, Germany
Elect. Energy	*Electrical Energy.* Morgan Brothers, 28 Essex Street, Strand, London, W.C. 2, England
Elect. Engg.	*Electrical Engineering.* American Institute of Electrical Engineers, 33 W. 39th Street, New York, N. Y.
Elect. Mfg.	*Electrical Manufacturing.* Gage Publishing Co., Inc., 1250 Sixth Avenue, New York 20, N. Y.
Electricity (USSR)	*Elektrichestvo.* Cherkasski Per, Moscow, USSR
Electronics	*Electronics.* McGraw-Hill Publishing Company, Inc., 330 W. 42nd Street, New York, N. Y.; Aldwych House, London, W.C. 2, England
Electrotechnika (Budapest)	*Electrotechnika.* V. Honved-u. 22, Budapest, Hungary
Elect. Times	*Electrical Times.* Sardinia House, Sardinia Street, London, W.C. 2, England
Elekt. Stantsii (USSR)	*Elektricheskie Stantsii.* Ministry of Electric Power Stations, GUM, III Korpus, Vetoshnyi Per, Moscow, USSR
EM (Vienna)	*Elektrotechnik und Maschinenbau.* Springer-Verlag, Molkerbastei 5, Vienna I, Austria
Energia Elett.	*Energia Elettrica.* Via Revere 14, Milan, Italy
Engineer	*Engineer.* 28 Essex Street, London, W.C. 2, England
ETZ	*Elektrotechnische Zeitschrift.* Verband Deutscher Elektrotechniker, Friedrich Ebert-Str. 111, Wuppertal-Elberfeld, Germany
Indust. Ital. Elettrotec.	*Industria Italiana Elettrotecnia.* Via Donizetti 30, Milan, Italy
Instrum. & Automation	Title extended from *Instruments*, 1954
Instruments	*Instruments.* Instruments Publishing Company, 921 Ridge Avenue, Pittsburgh 12, Pa.
IRE Conv. Record	*IRE Convention Record.* Institute of Radio Engineers, 1 E. 79th Street, New York, N. Y.
Iron & Steel Engr.	*Iron and Steel Engineer.* Association of Iron and Steel Engineers, 1010 Empire Building, Pittsburgh 22, Pa.
J. Brit. Instn. Radio Engrs.	*Journal*, British Institution of Radio Engineers, 9 Bedford Square, London, W.C. 1, England
J. Res. Nat. Bur. Stand.	*Journal of Research*, National Bureau of Standards, U. S. Government Printing Office, Washington 25, D. C.
Mullard Tech. Commun.	*Mullard Technical Communications.* Century House, Shaftesbury Avenue, London, W.C. 2, England
Nachrichtentechnik (Berlin)	*Nachrichtentechnik.* Verlag Technik, Unter den Linden 12, Berlin, N.W. 7, Germany
Nature	*Nature.* Macmillan & Company, Ltd., St. Martin's Street, London W.C. 2, England
OTS	*Office of Technical Services, Reports.* Department of Commerce, Washington 25, D. C.
Philips Tech. Rev.	*Philips Technical Review.* Philips' Gloeilampenfabrieken, Eindhoven, Holland
Proc. 1957 Elect. Comp. Symposium	*Proceedings*, 1957 Electronic Components Symposium, Institute of Radio Engineers, 1 E. 79th Street, New York 21, N. Y.
Proc. IEE	*Proceedings*, Institution of Electrical Engineers, Savoy Place, London, W.C. 2, England
Proc. IRE	*Proceedings*, Institute of Radio Engineers. 1 E. 79th Street, New York 21, N. Y.
Proc. STC on Mag. Amp., T-98	*Proceedings*, Special Technical Conference on Magnetic Amplifiers, *AIEE Special Publication T-98*, August 1957. American Institute of Electrical Engineers, 33 W. 39th Street, New York 18, N. Y.
Radio Engg. (USSR)	*Radiotekhnika.* ul. Kirova, 40, Moscow, USSR
Researches Electrotech. Lab. (Tokyo)	*Researches*, Electrotechnical Laboratory Agency of Industrial Science and Technology, Ministry of International Trade and Industry, 2-Chrome, Nagato-Machi, Chiyoda Ku, Tokyo, Japan
Rev. Élect. Mecan.	*Revue d'Électricité et de Mécanique.* Société Générale de Constructions Électriques et Mécaniques Alsthom, 38 Avenue Kléber, Paris (XVIᵉ), France
Siemens-Zs	*Siemens-Zeitschrift.* Siemens-Halske, Werner-Von Siemens-Str. 50, Erlangen, Germany
Trans., PG., IRE	*Transactions*, Professional Groups, Institute of Radio Engineers, 1 E. 79th Street, New York 21, N. Y.
VDE Fachberichte	*VDE Fachberichte.* VDE-Verlag, Friedrich-Ebert-Strasse 111, Wuppertal-Elberfeld, Germany
Westinghouse Engr.	*The Westinghouse Engineer.* 306 Fourth Avenue, Pittsburgh, Pa.

Reversible-Polarity D-C Power Amplifier Using Magnetic-Amplifier-Controlled Switched Transistors

N. L. SCHMITZ
MEMBER AIEE

T. BERNSTEIN
MEMBER AIEE

Synopsis: This paper describes, analyzes, and presents performance data on a reversible-polarity d-c power amplifier suitable for reversing drive of d-c motors in sizes up to 1 horsepower (limited only by presently available components) as well as for a wide range of additional applications including servomechanisms. Full-load and light-load efficiencies, output impedance, power gain, and other characteristics compare favorably with those of the rotating-amplifier-type motor-generator sets. The system under discussion, being completely static, can be expected to show significant advantages in reliability and ability to withstand a wide range of adverse environments. Limitations on size are practical rather than theoretical and may be expected to become less stringent as transistor technology improves and as further developments occur in areas such as switched silicon diodes.

THE PROBLEM of devising a high-efficiency magnetic-amplifier circuit with a reversible-polarity d-c output has been considered in some detail in the literature. Conventional reversible-polarity circuits[1,2] have a maximum theoretical efficiency of 50% as compared to 100% for the circuit to be considered. The increase in efficiency is accomplished by using switched transistors in conjunction with magnetic amplifiers. Previous applications of switched transistors[3] have had magnetic-amplifier gate windings in series with the transistors. Such circuits have the disadvantage of requiring the use of power magnetic amplifiers.

The advantages of operating transistors in their switching mode are well known.[4] These advantages include small power loss and consequent low temperature rise. Since the output of a self-saturating magnetic amplifier is a switched form of sine wave, it is well suited for control of transistors in their switching mode. In such a scheme the transistors control the load power while the magnetic-amplifier output power need only be sufficient to control the transistors. The use of switching transistors controlled by magnetic amplifiers rather than an all-transistor circuit can be justified in that the most important advantages of magnetic-amplifier control such as isolated, multiple inputs are retained.

Basic Circuit

Fig. 1 is a schematic representation of the basic circuit for providing reversible-polarity direct current for a 2-terminal load. The magnetic amplifiers are designed for d-c output and are biased to cutoff. Ideally, there is no base drive in the transistors under quiescent conditions and both transistors are nonconducting.

In actual operation, however, the exciting current required by the magnetic-amplifier cores at cutoff prevents this condition from being realized completely. Failure to render both transistors nonconducting under quiescent conditions results in an undesirably large circulating current and a balancing problem.[5] This effect can be minimized as outlined in Appendix I.

The control windings of the magnetic amplifiers are so interconnected that one polarity of control voltage will aid the bias on one amplifier and oppose the bias on the second. Reversed polarity of control voltage reverses this action. With a given polarity of control, the output of one magnetic amplifier provides base drive to the transistor and causes it to be switched on at a phase angle dependent on the magnitude of control signal. This switched output of the transistor then appears across the load.

Since the transistors are switched either fully off or fully on there is no gain-balancing problem associated with the use of the transistors. Based on the rms value of the output voltage the maximum theoretical efficiency is 100%.

Efficiency, %, based on measured power	78.5	79.4	76.6		71.5	60

Reversible-Polarity Circuit

Using the magnetic amplifier and transistor circuit of Fig. 1, the experimental circuit shown in Fig. 2 was developed. In order to provide a higher load voltage, two transistors are cascaded for each polarity of output. With transistors having suitably high voltage ratings, only one is required for each polarity of output. The 10,000-ohm resistors, R_1, across each transistor insure good voltage division. Additional transistors can be cascaded with the addition of load windings to the magnetic-amplifier core. The magnetic amplifiers are those discussed in Appendixes I and II.

The transfer characteristics (Fig. 3) of output voltage versus control current are dependent on the bias current. Too much bias current, shown by curve *A*, produces a dead zone about the zero control-current operating point. Too little bias current causes a large circulating current. With an ideal bias as shown by curve *B* there is some circulating current but it is not excessive. The 0.5-ohm resistors, R_4, of Fig. 2 tend to limit this current.

Experimental Results

Efficiency

The efficiency of the circuit of Fig. 2 was measured using the components itemized in Appendix II.

Comparisons as to efficiency require a definition of terms. If a lossless circuit has a perfect full-wave rectified output, its output based on the product of average current and voltage is only 80.9% of the a-c power input. A wattmeter indication of load power includes losses caused by the a-c components of voltage and current in addition to the product of average voltage and current. In applications where the load is the armature of a motor with a separately excited field, it would seem that the useful output to be considered is that contributed only by the average components of the voltage and current. Table I lists the test results obtained using the circuit of Fig. 2.

Regulation

The problem of regulation of the output voltage under changing load becomes quite important when the load is a separately excited shunt motor. Under starting conditions the load current is large. Unless accompanied by sufficient base current, large load currents can cause the transistor to operate in the nonswitching mode. This mode of operation results in increased emitter-to-collector voltages which can cause excessive voltage regulation and excessive power dissipation in the transistor.

Fig. 4 shows the effect of base current

level upon voltage regulation. The sharp dropoff appearing in these characteristics results from the transistor being driven out of its switching mode as load current is increased. This effect can be minimized as shown by the dashed curves, by reducing the base circuit resistance and thereby increasing the base drive. Dropoff is still apparent at late firing angles (small control currents) because of the high peak currents required for a given average value of current.

Conclusions

The circuit of Fig. 2 lends itself well to the use of existing components. For higher current output, transistors can be paralleled without requiring additional magnetic amplifiers. For higher voltage applications transistors can be cascaded as shown at the expense of additional load windings on the magnetic amplifiers and on the small magnetic-amplifier supply transformer.

In the design of the magnetic amplifiers, the cores should be as small as possible. This reduces the exciting current and control power. The smaller cores also result in more rapid response. The voltage output of the magnetic amplifier need only be sufficient to drive sufficient current through the base to switch the transistor under the largest required load-current condition.

Appendix I. Effects of Exciting Current

For self-saturating magnetic-amplifier circuits such as the full-wave bridge or center-tap d-c output circuits, the output is never cut off completely because of the core exciting current which still appears at minimum output. Normally this is not a problem in a magnetic-amplifier circuit since the exciting current is usually quite small compared to the outputs desired. When this exciting current appears as base drive for a grounded-emitter transistor, however, it is multiplied by a factor having the order of 100 for large power transistors and appears in the collector load circuit. This causes a circulating current through the transistors even though the magnetic amplifiers are cut off.

Such a circulating current has two major disadvantages:

1. Unbalance in the gain of the transistors causes a voltage to appear on the load with no control signal.

2. The transistors are not operating in a switching mode since they are not completely cut off. Appreciable transistor heating is thus caused by the circulating current.

The exciting current problem can be minimized by using the smallest magnetic-amplifier cores possible and by using core materials such as Hy Mu-80 or Permalloy, both of which require very low exciting currents.

A further step towards alleviating the exciting current problem is shown in Fig. 5. The basic magnetic amplifier in Fig. 5 is a center-tap d-c magnetic amplifier providing base drive for the transistor through the 235-ohm resistor. With zero control signal, the exciting current of the magnetic amplifier appears in the 235-ohm base resistor. The emitter-to-base current can be reduced by shunting part of the exciting current through the 220-ohm resistor as shown. The magnetic amplifier must be designed to provide sufficient output current to drive the transistor into its "switched-on" mode with the parallel resistor shunting part of the base drive.

To reduce the collector current still further, the two diodes and 4,700-ohm resistors are added in Fig. 5 to form a bridge circuit with the 4,700-ohm resistors chosen so as approximately to equal the unsaturated impedance of the cores. This further addition has negligible effect on the normal operation of the circuit but does reduce the exciting current to a condition under which the exciting current is no longer a problem. Fig. 6 shows the three conditions for: (1) collector current caused by the exciting current (with no shunting resistor or balancing bridge); (2) shunting resistor alone; and (3) with the shunting resistor and balancing bridge connected in the circuit.

Use of biased diodes with a separate, isolated d-c supply has also been proposed as a solution to the exciting current problem.[5]

Discussion

M. G. Rekoff, Jr. (Carl C. Crane, Inc., Madison, Wis.): The authors have made an interesting contribution to the rapidly expanding field of switched transistors with this paper. There is one point that is

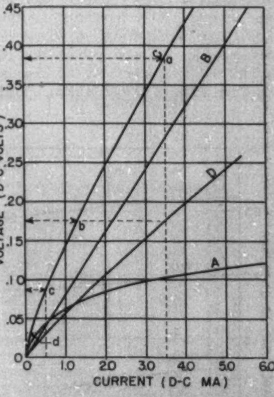

Fig. 7. Voltage-current characteristic used to determine transistor base current under shunted conditions

A—DT-100 transistor emitter-base junction
B—80-ohm resistor
C—80-ohm resistor in series with DT-100 emitter-base junction
D—80-ohm resistor in parallel with series combination of an 80-ohm resistor and DT-100 emitter-base junction

not clear; that is the effect of the emitter-to-base shunting resistance upon the emitter current. Since the resistance of the emitter-base junction is nonlinear the current will not divide directly proportional to the value of the base and shunting resistances. Fig. 6 seems to illustrate this effect since, although the shunting and base resistances are approximately equal, the collector current after shunting is less than half of the original current value.

Would the authors care to comment or elaborate on that facet of the circuit operation?

N. L. Schmitz and T. Bernstein: The effect of the emitter-to-base shunting resistor is difficult to analyze except by graphical means because of the nonlinear characteristics of the emitter-to-base junction. In Fig. 7, curve *A* represents the emitter-to-base current-versus-voltage characteristic for a typical *DT-100* germanium transistor while curve *B* represents an 80-ohm resistance characteristic. Using this emitter-to-base and resistance characteristic, the combined characteristic, *C*, of this junction characteristic in series with the 80-ohm resistor is constructed. The final characteristic, *D*, is constructed to show the current-versus-voltage characteristic of *C* in parallel with the 80-ohm resistor. This characteristic, *D*, now shows the plot of current versus voltage for the emitter-base junction in series with an 80-ohm resistor and the combination in parallel with an 80-ohm resistor. The exciting current output of the magnetic amplifier can be considered as a constant current source. The important component of this current is the current through the emitter-base junction since this current is multiplied by β, approximately 100, to obtain the collector current at minimum output.

If the size of the core and number of load turns were such as to provide 3.5 milliamperes of exciting current, then with no shunting resistor the current through the emitter base junction is 3.5 milliamperes as shown by point *a* on curve *C*. If there is an 80-ohm shunting resistor used then the exciting current through the junction is approximately 1.3 milliamperes as shown by point *b* of curve *C*. A lower shunting resistor might be used but then at maximum output more than half the control current would be diverted around the junction with a consequent loss in efficiency. For low exciting currents, for example 500 microamperes, the reduction in exciting current through the junction is more pronounced when shunting resistance is used because of the nonlinearity of the curves at low currents. This is shown at points *c* and *d* on curve *C*.

Another approach to the exciting current problem suggested by Prof. R. A. Greiner of the University of Wisconsin is to shunt only the emitter-base junction with a resistor rather than shunting the junction in series with a base resistor. By a graphical construction similar to the methods used in Fig. 7, shunting the emitter-base junction with a 10-ohm resistor while maintaining an 80-ohm resistor in the base circuit will reduce a 3.5-milliampere emitter-base current to approximately 0.25 milliampere. This result was also verified experimentally. The disadvantage of this method is that less current is driven through the emitter-to-base junction when the magnetic amplifier fires.

LATE DISCUSSIONS

Discussion of The Ferroresonant Circuit, George E. Kelly, Jr., pages 843–48.

C. F. Spitzer (Lockheed Aircraft Corporation, Palo Alto, Calif.): I concur fully with the author's statement that better agreement between analytically predicted results and experiment will be derived from a careful consideration of the harmonic components of current. This is, of course, primarily true for operation in the high-current condition, in which the inductor undergoes saturation in every cycle. Some simplified approaches to this problem have been discussed in the literature,[1,2] and a direct application to the simple resistance-inductance-capacitance version of the ferroresonant electric circuit is very readily made. An experimental confirmation of this need to include the harmonics is found in the difference between calculated and experimental values for essentially all circuit configurations tested by Mr. Kelly. The improved approximation which results from the neglect of circuit resistance can possibly be explained as follows: Neglect of resistance tends to raise the calculated value, thus compensating for the neglect of the harmonics of current which would also tend to raise the calculated value. Needless to say, considerations of harmonics would have been much closer to reality.

In its review of the history of the problem of ferroresonance the author refers to the Odessey-Weber paper (see reference 5 of the paper). It should be noted that the first method Mr. Kelly uses is identical with equation 2 in the Odessey and Weber treatment:

$$E=\sqrt{(IR)^2+\left(E_2-\frac{1}{\omega C}\right)^2}$$

although a comparison of experimental with analytically obtained results is not made there. However, the following statement follows this equation:

> A refinement of this method, due to Rouelle (see reference 3 of this discussion) requires the separation of the reactor voltage into active and reactive components on the basis of fundamental frequency. A predetermination of the operating characteristics shows good agreement with experimental results.

It thus appears from this description that Rouelle used to good advantage the second method described by Mr. Kelly, whose results appear to confirm those obtained by Rouelle.

I have found the fleeting reference to the ferroresonant state of a 3-phase 4-wire Y-connection of considerable interest, and should have greatly preferred to see the emphasis of Mr. Kelly's paper placed on this topic and on related problems of 2- and 3-phase systems with open lines, unbalanced or open loads, and open neutral. Quite possibly an extension of the method of symmetrical components could be developed, taking due account of the harmonic components of currents. Admittedly, this is a more demanding task than the approach to the simple resistance-inductance-capacitance circuit but, by the same token, it should also be much more rewarding.

Discussion of Radio Attenuation at 11 Kmc and Some Implications Affecting Relay System Engineering, S. D. Hathaway, H. W. Evans, pages 930–38.

H. C. Franke (Bell Telephone Laboratories, Inc., Whippany, N. J.): This paper is one of the first attempts to present path performance suitable for engineering of microwave radio systems operating in the 11-kmc region.

The information which is presented should add to the wealth of data already available in other regions of the microwave spectrum and thereby aid the system engineer in further extrapolating on the suitability of higher frequency ranges for radio-relay communication.

While these test data are fairly complete, it is unfortunate to note that one very important type of test had been omitted as stated in the text of the paper. Additional path loss tests besides those with fixed antennas give considerable increased background of the propagation characteristics over the path. These tests are usually conducted by a series of observations of antenna height versus loss as measured by the received field strength. Such measurements include considerations of the relative height of each antenna as determined from an examination of the path geometry which includes height of each site, clearance over the intervening obstructions, and the desired clearance over the path. For an experiment of this type as many related factors as possible should be explored so that more complete data are available which should lead to better understanding of the effects of site selection, path clearance, effect of vegetation, etc. It is generally conceded that, in so far as possible, reflections on microwave paths should be avoided, since this secondary effect may increase the depth of fade and thereby result in poorer performance. Generally, from an examination of the path topography, tentative conclusions may be reached as to the possibility of reflections; particularly conducive to such conditions are flat barren areas or large bodies of water. While the test area appears to have considerable surface roughness when related to the wavelength of the frequency used, in this case equal to about one inch, the possibility of side reflections from man-made and natural smooth obstructions located in the path should not be ruled out.

While the attenuation due to rain is severe at these frequencies as pointed out in the data, it should be noted that during these periods the air is generally well mixed, and the possibility of selective fading due to reflections from atmospheric discontinuities is relatively small. Hence at any given time either fading loss due to multipath transmission or attenuation due to rain loss is present, but not both simultaneously. Therefore, the equipment margins need only consider the more severe condition.

Discussion of Reactions of Bistable B-H Loops on Magnetic Amplifiers, R. E. Morgan, Communication and Electronics, November 1958, pages 586–90.

T. Bernstein and **K. Mei** (University of Wisconsin, Madison, Wis.): Mr. Morgan's discussion of the possible connection between the bistable **B-H** loops of the core and the instability of magnetic amplifiers at reduced voltage is an interesting study concerning an old problem. It seemed worth while to correlate this connection by investigating various materials to see if the instability occurs only when bistable **B-H** loops are evident.

Along this line of investigation, four samples each of 2-mil squared permalloy, permalloy, Deltamax, and L Silectron were wound and connected in a doubler circuit with a-c output. The cores used were Arnold Engineering *1T4180* with load and control windings each of 1,000 turns American wire gauge no. *25*. The excitation frequency was 60 cycles per second. Examining the flux-current loops of the cores alone after a d-c bias had been applied and removed, it was observed that all the Deltamax cores exhibited the bistable **B-H** loops while none of the other cores did. Operating the doubler circuit at 10% below the cores' saturation voltage, a criterion was established where the voltage output across the load resistor after the snap-up was compared to the zero control current voltage output. For control, a d-c power supply in series with a 10,000-ohm resistor was used while the load resistor was 100 ohms. Silicon diodes were used for the rectifiers.

Table I

Core Material	Voltage After Snap as Percentage of Zero Control
Squared permalloy	62.5
Permalloy	no snap
Deltamax	16.7
L Silectron	95

The results were as shown in Table I.

The interesting result is the lack of correlation between bistable loops and the instability. The results with the Silectron are particularly surprising. Has the author investigated any other core materials in the pulse-type circuit to see whether there is still instability even though there are no bistable **B-H** loops?

The author states, "From 12 cores selected at random, 8 of the cores have **B-H** loops (exhibiting bistable characteristics) while the remaining 4 cores have symmetrical minor **B-H** loops . . ." Were the four cores used in the circuit to see if they also caused instability? It would seem that cores which have more than two stable minor loops might exhibit more than one region of instability. Have such results ever been observed?
